THE ANATOMICAL RECORD, VOL. 19, NO. 1
JUNE, 1920

Resumen por el autor, John Shelton Horsley, Jr.,
Universidad de Virginia.

Descripción de un perro con seis patas.

El presente trabajo es una descripción detallada de la anatomía externa e interna de una perra jóven que poseía un par adicional de patas posteriores bastante normales y colocadas simétricamente. Este mónstruo presentaba un par de pelvis casi normales fusionadas entre sí, una cloaca en el lado derecho, ano y vagina separados en el lado izquierdo, dos vejigas urinarias, un solo riñón, un uréter impar en conexión con la vejiga izquierda, un solo intestino delgado, dos colon, dos ciegos con sus correspondientes apéndices, glándulas suprarrenales pares y dos úteros provistos cada uno de un tubo uterino y un ovario. Las tibias de las patas supernumerarias estaban fusionadas.

BY THE BIBLIOGRAPHIC SERVICE, MAY 10

A DESCRIPTION OF A SIX-LEGGED DOG

JOHN SHELTON HORSLEY, JR.
Department of Anatomy, University of Virginia

SIXTEEN FIGURES

On January 11, 1919, Mr. John R. Raines, a farmer living near the University, brought to Prof. H. E. Jordan's laboratory a dead female dog with an extra pair of hind legs. The thoracic and abdomnial cavities were opened and the dog at once placed in a 10 per cent solution of formalin. This specimen was subsequently turned over to me for study and description. The work was done in the Laboratory of Histology and Embryology under the supervision of Professor Jordan, to whom I am greatly indebted for the privilege.

From Mr. Raines were secured the following data: The dog was born October 7, 1918; died from exposure to cold the night of January 9, 1919. Her father was a shepherd, her mother a bull-terrier; both parents were apparently normal. The litter included in addition to this abnormal individual one normal brother and three normal sisters. The six-legged puppy appeared in life otherwise normal and healthy, and was apparently but little inconvenienced in walking and running by the extra pair of legs, which she carried slightly raised above the ground. The unpaired tail was apparently under perfect control.

EXTERNAL APPEARANCE

As regards the shape and general appearance of the head this dog more nearly resembled a fox-terrier, and she was about the size of this type of dog (fig. 1). With the exception of the nipples, she appeared normal cephalad of the umbilicus. With the exception of the tail and anus, she was double caudad of this point.

Closer examination revealed the following details: The leg, vagina, anus, and tail of the left side were displaced about 1 cm. laterad of their normal relative position with respect to the vertebral column. The sagittal plane of the proximal portion of the tail made an angle of 25 degrees with that of the vertebral column. The right leg was displaced slightly forward and dextrad of its normal position. It was slightly smaller than the left leg and presented a rather undeveloped appearance, especially in the size of the thigh muscles. Between these two legs hung the extra pair of legs. The pair was inclined a little to the right of the medial line and it was enveloped in a common integument as far distally as the ankles. The members of the pair were of approximately equal size and represented genuine hind legs. Barring a very slight ventral bend at the level of the knees, the pair was extended in a straight line and it was placed in such a way that the pads of the feet faced toward the ground when the dog was standing. The pair measured 18.5 cm. from the heads of the femurs to the tips of the toes. These extra legs were only slightly more slender and shorter than the other two hind legs. Palpation indicated a fusion of the tibiae, a conclusion confirmed by roentgenograms (figs. 2 and 3) and subsequent dissection. The extra legs articulated with the medial surfaces of the opposite halves of the paired pelves slightly forward, and to the right, of the root of the tail. There was no second tail or anus, but there was a second set of external genitalia 2 cm. below and to the right of the articulations of the extra pair of legs. The vertebral column in the region of the sacrum seemed abnormally wide on the right side and presented abnormal landmarks, description of which will be reverted to subsequently. Just below the right side of the double knee there was a roughened scarlike area, whose significance will also be indicated below.

INTERNAL ANATOMY

Osteology

The vertebral column contained the usual number of vertebrae, namely seven cervical, thirteen thoracic, seven lumbar, three sacral, and nineteen caudal (fig. 2). It remained single throughout and was normal as far as the seventh lumbar vertebra, which latter was normal on the left side, but presented a large well-rounded mammillary process that was twisted dorsally and slightly caudally extending on the same level with that of the corresponding vertebral spine. The sacrum was very slightly bent to the left. On the right the articular surface of the first sacral vertebra was turned dorsally, and accordingly produced a slight elevation. There was also on the right side an oblong, irregular plate of bone that measured 10 mm. in length, 7 mm. in thickness, and 6 mm. in the vertical plane (fig. 4, *M*). It was fused with the first and second sacral vertebrae, and represented a second deformed sacrum. On the left side the sacropelvic articulation was normal with the exception of a small piece of bone, 8 mm. in length, which jutted out caudally from the left ilium at the level of the sacrum and was fused with the second and third sacral vertebrae. There was a gentle curve to the left, formed by the first three caudal vertebrae, the first of which articulated on its right side with the base of the fused ilia. The remaining caudal vertebrae were normal.

Two pelves were present (fig. 3). At first observation there seemed to be a smaller medial pelvis fused dorsally to a larger and practically normal ventral pelvis; but after closer examination of all of the related structures the conclusion was reached that the condition was one of lateral fusion between a right and left pelvis. The course of the unpaired sciatic nerve is the only obstacle to the latter interpretation. The right and left lateral ilia were of normal size (figs. 4 and 5). The left ilium articulated with the sacrum of the left side in the usual manner, with the exception of the intervention of a small spur of bone extending caudally from it. This has already been described. The crest of the right ilium was displaced cephalicly 1 cm. and dorsally

3 mm. A small triangular piece of bone, 1.5 cm. in length, articulated with the right deformed sacrum by a number of strong ligaments forming an amphiarthrosis (fig. 4 *N*). The crests of these lateral ilia were about 6 mm. further apart than they should have been if the right had its normal position and the two considered part of one pelvis.

The right and left medial ilia were fused to form one bone which presented a dorsally protruding crest (fig. 4). This fused medial ilium was approximately a third the size of the normal lateral ilia. The vestigial right sacrum was fused with the base of the medial fused ilium. These two structures were continuous on the ventral surface, but dorsally there was a depression partially separating them. On the left the base of the fused ilium was joined to the third sacral vertebra by a synchondrosis, and with the first (proximal) caudal vertebra by a syndesmosis. This fusion of the ilia had brought the two medial acetabula so close together on the dorsal surface that they nearly touched each other (fig. 5). The long axis of this medially fused ilial portion of the compound pelvis made a 15 degree angle with the midline on the right side. If considered as a dorsally interpolated pelvis, it would be about half the size of the larger pelvis.

The two medial ischia formed a basin, which was open dorsocaudally and closed ventrocephalicly, presenting on each side the relatively high crests of the two medial tubera ischii. The basin measured 3.7 cm. from crest to crest (fig. 5). In this basin lay the necks and proximal fourths of the femurs of the extra two legs, along with that portion of the heads that did not enter directly into the hip-joints (fig. 4). The two obturator foramina opened ventrocephalicly through each side. They were completely closed by thin ligamentous bands and were of about half the normal size. Caudal to the fusion of the medial ilia, and also to the acetabula, there was a very firm union between the right and left pelves along the whole length of the pubo-ischial symphysis of each (fig. 5). This line of fusion would call for the same description whether the fused pelves were interpreted as right and left or dorsal and ventral components.

The heads of the femurs of the extra two legs were about 1 mm. apart and articulated with the two medial acetabula, each forming an enarthrosis. The articulations were alike on both sides, and normal to the extent that they formed ball-and-socket joints, with synovial bursae, ligamentous capsules, etc. There was a slight twisting, however, produced by their abnormal positions. All of the structures that entered into these articulations were of approximately half the size of the corresponding structures of the normal right and left lateral hip-joint. The movements of these articulations were limited practically to a dorsoventral action due to the fusion of the tibiae of the two extra legs (fig. 3).

The right and left lateral ischia were of normal size, but were slightly twisted laterally, the right more so than the left. The crest of the right lateral tuber ischii was 1 cm. laterad of that of the right medial tuber ischii at the widest point (fig. 4). The right colon, vagina, and urethra united within the basin formed by these ischia into a cloaca (fig. 12). The opening of this basin was the pelvic mouth of the right pelvis. The corresponding crests of the left side were 2 cm. apart at their widest points and formed a somewhat less constricted basin for the left vagina. The aperture of this basin was the pelvic mouth of the left pelvis (fig. 5).

The bones of the right and left lateral legs were normal. Those of the extra two medial legs were very slightly shorter and slightly more slender than the lateral ones, as may be seen in figure 3. The tibiae of the supernumerary legs were fused medially along their whole extent. The fibulae appeared slightly larger than normal, the left fibula being more intimately fused with its tibia (fig. 3). No other marked abnormalities occurred in the bony structures. The double knee-joint was practically immobile except for a very slight action in the caudocephalic direction.

Myology

The muscles of the left lateral leg, thigh, and hip regions were normal; those of the right thigh also appeared normal except for a somewhat smaller size.

In the hip region of the two extra legs there occurred only a very few small muscles that passed down to the thigh. These muscles were inserted along the proximal portions of the two femurs and seemed to represent only remnants. There was a layer of superficial fascia over the whole of this muscle mass. Some atrophic vestigial muscles covered the popliteal fossae extending up over the distal two-thirds of the two femurs and down well over the ventral portion of the knee-joint. They were better developed on the left member than on the right. The space between the two femurs was occupied by an artery, a vein, a large nerve, and an abundance of loose connective tissue. The two legs of the extra pair were bound together by a superficial layer of fascia and the integument. There were two very distinct tendons of Achilles; the one of the left leg was more pronounced, and it was stretched so tight as to permit only very little movement of the left foot. The right foot was more free to move. The flexor digitorum brevis tendons were very distinct on the feet, but none of the muscles could be found. No muscles occurred beyond the extreme proximal ends of the fused tibiae; there was an enveloping layer of superficial fascia along their entire length.

The ligamentum nuchae was the only abnormal structure observed cephalad of the diaphragm. This was a very thick, round ligament rather than, as usual, a thin ligamentous raphé.

Splanchnology

The stomach, small intestines, liver, gall-bladder, spleen, and pancreas were unpaired and apparently normal.

The large intestines were double; one colon was very much distended and lay ventrad and to the right of a smaller colon (figs. 6, 7, and 8). The former had very short ascending and transverse portions, but a long descending portion which was constricted in the middle. This constriction produced two large sacculations, the caudal being the more distended. The wall of this portion was rigid and brittle, apparently lacking muscle constituents. This larger colon passed through the right pelvic

mouth and opened into the vagina of the right side, thus contributing to the formation of a cloaca. The smaller colon of the left side had neither teniae nor sacculations; and there were practically no corresponding ascending or transverse portions. It joined a normal rectum which ended in a normal anus; it was on the whole more nearly normal than the right colon. Feces were found in both colons, and there were no adhesions or constrictions that could hinder either from functioning.

The iliocolic portion of the small intestine was slightly enlarged, and at this point of enlargement the two colons anastomosed with each other and with the small intestine (fig. 6). Each colon had a caecum with an appendix. The right caecum was the larger and, excepting its increased size and its associated appendix, it seemed normal. This appendix was a constricted apical portion of about 1.5 cm. in length (fig. 6). The left caecum was very short, being about 1 cm. long. Its appendix had a smaller diameter than that of the right and was about three times as long (fig. 7). It was sharply folded at four distinct points into a compact structure.

The single ileocolic valve was relatively large and covered both colic orifices, but was thickened in that portion overlying the right orifice (fig. 8). Its opening was directed somewhat laterally and gave vent nearly directly into the left colon. At a point immediately distal to the valve the lumens of the two colons united. On account of the thickening of one side of the valve, the connection between the lumens of the right colon and the small intestine was thrown to the left, somewhat toward the smaller colon. The caecocolic orifices of both colons were apparently normal (fig. 8). It may be of interest to note that there were ten persimmon seeds and a few whole grains of corn in the right colon. The great enlargement of the right colon may find its explanation in a gradual distention by fecal contents which could be only slowly voided due to lack of peristalsis following the paucity or lack of smooth muscle.

On the right side the larger colon, the urethra, and the vagina had a common exit chamber, forming a cloaca (fig. 12). The right rectum formed the largest part of this chamber, and on

this account the orifices of the vagina and the urethra seemed to empty into it at a point about 3 cm. cephalad of the common external opening, the vagina on the medial and the urethra on the lateral sides, respectively.

The external genitalia of that side were slightly smaller than those of the left, but had a generally normal appearance.

The urogenital system

The single kidney was situated on the left side. No trace of even a vestigial kidney could be found on the opposite side. This lone kidney, located at the usual level, was considerably larger and more spheroidal than normal (fig. 9). It received a large renal vein from the left side of the inferior vena cava; and slightly dorsad and caudad of this point it received a renal artery from the abdominal aorta. Midway between the latter and the pelvis of the kidney the renal artery divided into two, one entering dorsally and the other, after curving around the renal vein, entering ventrally and cephalicly to it. Before entering the pelvis the renal vein gave off a branch that coursed laterally over the ventrocaudal portion of the kidney to the left ovary and oviduct. A single large ureter passed caudally to empty into the left urinary bladder in a normal way (fig. 10). The minute anatomy of this kidney was perfectly normal. Cephalad of the kidney, and in their proper positions, occurred two adrenals (fig. 9).

Of the two urinary bladders the left was apparently normal, except that it was slightly displaced to the left. The displacement was due chiefly to the presence of the greatly distended right colon. This bladder was completely collapsed. Its urethra was normal, emptying by means of the left vagina (fig. 10). The right urinary bladder was rigid and distended. It was composed of brittle tissue apparently like that of the larger colon. It was obviously smaller than the left bladder when the latter had become distended. At its cephalic end there was a narrow circular area (3 mm. in diameter) of very delicate tissue simulating a membrane, which yielded on the slightest pressure (fig.

11). There was no vestige of a ureter in connection with this bladder. Its urethra had about twice the normal diameter, and was composed of the same kind of brittle tissue as the bladder. A medial longitudinal section of the bladder revealed a lining of elastic tissue that was hard to peel off and that had the macroscopic appearance and general consistency of a thin plate of cartilage. Irregular partitions extended from the walls forming two large pockets at the cephalic and caudal ends of the bladder, respectively (fig. 11). Between these and in the central portion there were about ten smaller pockets. Along the entire ventral wall there was a space between this cartilage-like lining and the wall of the bladder which was continuous with the lumen of the urethra (fig. 11). The urethra had a very thick wall and emptied into the cloaca (fig. 12).

The genital organs

Two ovaries, each with its respective uterine tube (unpaired cornu uteri) leading to a respective uterus (corpus uteri), were situated in their normal positions. The ovary of the left side was flattened and oval in outline; that of the right side was flattened, elongated, and almost crescent-shaped, with a deep longitudinal groove extending over its lateroventral surface. The two uterine tubes extended caudomedially to their corresponding uteri (figs. 12 and 13). The right tube was the shorter and slightly the thicker of the two. The right uterus was about twice as long and thick as the left. The latter presented no peculiarities in its continuation into the vagina of the left side. The right vagina was relatively short; it was continued into the common chamber which formed the cloaca. Both uteri were abnormal to the extent that they were unicornuate.

Four rows of asymmetrically distributed nipples, twelve in number, were present (fig. 14).

Angiology

The blood supply of the kidney has been described above. No traces of any blood-vessels that might have corresponded to the right renal artery and vein could be found.

The abdominal aorta and the inferior vena cava remained single throughout their entire course, but they gave off extra branches which supplied the supernumerary structures. The distribution of these two chief vessels and their principal branches is shown in figure 15. The abdominal aorta gave off a right common iliac artery a short distance cephalad of its usual place of branching. The left common iliac was larger than the right and seemed to represent a direct continuation of the abdominal aorta. Its course was in direct line with that of the aorta to a point about 1 cm. caudad of the point of branching of the right common iliac. Here there was a gentle curve to the left, the main portion being continued as the left external iliac which proceeded down the left lateral leg as the femoral artery. Slightly caudal to the beginning of this curve on the left common iliac just mentioned, and on the outside of it, a large branch came off which supplied the two extra legs. Very close to the origin of this larger branch there was a small branch which went to the left urinary bladder; while just caudal to this a larger one came off and divided into two, the medial representing the caudal (middle sacral) and going to the tail, the lateral going to the structures in the left pelvic cavity and probably representing the left internal iliac artery.

One principal artery and one principal vein supplied the two extra legs. The plan of the arterial supply is represented in figure 16; that of the venous supply is practically indentical. The vessels continued their course caudally between the two femurs, giving off two small branches, one on each side, just distal to the heads of the femurs, to supply the scanty muscles and fascia of that region. No other branches were discernible cephalad of a level about 2 cm. proximal to the knee-joint. At this point, however, both the artery and the vein divided into one medial and two lateral branches, the two lateral branches of

each vessel passing distally to the lateral sides of the fused tibiae and finally coming around on the dorsal side to form an anastomosing arch over the distal portion of the tibiae in the region of the ankle. From this arch sprang two main arteries and veins which passed on to supply the feet, the right set to the right foot and the left set to the left foot. Two medial smaller branches arose from the arch and supplied the structures in the immediate vicinity. The medial branch (fig. 16 *M*) of the principal vessels mentioned above represented a terminal branch. The medial artery and vein passed distally along the ventral line of fusion of the two tibiae where they became resolved into branches that supplied the structures of the ventral portion of the fused legs. The lateral branches supplied the structures of the lateral and dorsal surfaces. The venous system of the supernumerary legs paralleled the arterial system throughout its entire course.

Numerous lymph nodes were found scattered throughout the abdomen. Just cephalad of the kidney occurred the two largest nodes. The smaller nodes were relatively more abundant along the inferior vena cava and the abdominal aorta. Those of the paired pelvic cavities were rather large and numerous. A large bean-shaped lymph node, about 1 cm. in length, was situated at the level of the stifle-joint on the ventral side. This probably represented a composite popliteal node and was apparently the only lymph node of the two extra legs.

Neurology

A large nerve accompanied the principal artery and vein of the two extra legs. This nerve presented an oval cystic enlargement, macroscopically suggestive of a ganglion, at the point where it entered the double leg, just distal to the heads of the two femurs. The nerve passed dorsal to the blood-vessels, accompanying them as far as they went, and then accompanying the terminal or medial branch down over the midline of the double stifle-joint. As the nerve passed the latter point it presented a gradual cone-shaped enlargement and, turning laterally and dorsally around the medial condyle of the head of the

right tibia, ended abruptly in the skin (fig. 16). On the external surface of the skin this termination presented a roughened scar-like appearance, the size of which was approximately that of the diameter of the nerve. Three smaller scar-like patches occurred below, and slightly medial to the principal one. No nerve fibers could be traced within the skin. The whole appearance of this nerve termination seems exactly what might have been expected if the nerve had penetrated the skin and its external part had subsequently sloughed off, thus leaving a scar with the nerve firmly attached. The proximal part of this nerve was attached to the right wall of the cavity through which it coursed to the extra legs in company with the two main blood-vessels. This attachment was made by strands of tissue chiefly to the middle portion of the small opening. The portion of the nerve from the cyst forward consisted of a hollow, circular strand of tissue that tapered down almost to nothing. There remained no connection with the spinal cord. This nerve probably represented fused right and left medial sciatic nerves.

CONCLUSIONS

Viewing the double portion of this dog, it is seen that the left component is more fully developed and that it is nearly in normal position, while the right component is entirely at the right of the median plane. The blood-vascular, the digestive, and the urogenital systems, excepting the kidney, and the fusions and articulations of the pelvic limbs, all consistently support an interpretation of this monster in terms of a side-to-side pelvic fusion of twin primordia, with complete resorption of the prediaphragmatic portions. A variant of this interpretation might be based upon the supposition that an original unpaired embryonic disc suffered a caudal splitting to the point including the primordia of the pelves. It is not possible with the available data to decide finally between the suggested alternatives of fusion and splitting. However, the mixed character of the abdominal viscera (e.g., single kidney, double colon) seems to favor the interpretation of fusion rather than of splitting. The

one chief objection to the interpretation of lateral, as opposed to dorsoventral, fusion is the presence of the unpaired sciatic nerve of the extra two legs. It the interpretation of lateral fusion is accepted, then the compound sciatic nerve seems to be greatly displaced. The sciatic nerve normally passes through the pelvic mouth and then courses laterally over the acetabulum on down the leg. The sciatic nerve of the right and left lateral legs followed this normal course. The fused sciatic nerves of the supernumerary limbs, however, entered the pair by a single root, having passed thither between the two medial acetabula, and not, as normally, through their respective pelvic mouths. The apparently ectopic position of the fused sciatic nerves can be explained on the very probable supposition that the primordia of the originally paired medial sciatic nerves fused before the medial components of the pelves had developed beyond their blastemal stage. This explanation becomes the more plausible when it is recalled that the fused sciatic nerves had suffered degeneration at their proximal ends, due in all probability to pressure here following the further development and subsequent fusion of the two medial components of the right and left pelves.

This dog belongs in the category of duplicate monsters designated dipygus dibrachius tetrapus, and corresponds in general to the six-legged rat recently described by Conrow[1] and more closely to certain human monsters described under this designation by Broman.[2]

Resumen por el autor, Howard B. Adelmann,
Universidad Cornell, Ithaca.

Un caso extremo de espina bífida con hernia dorsal en la ternera.

El presente trabajo es una descripción de un caso en el cual una porción de la membrana mucosa intestinal emerge del cuerpo a través de un orificio situado en la región lumbar de la columna vertebral. Este defecto es una consecuencia de un defecto en la linea primitiva.

AN EXTREME CASE OF SPINA BIFIDA WITH DORSAL HERNIA IN A CALF

HOWARD B. ADELMANN

Department of Histology and Embryology, Cornell University, Ithaca, New York

TWO FIGURES

The foetus forming the subject of this note is a part of the collection in obstetrics of the New York State Veterinary College and was submitted to me by Dr. B. F. Kingsbury for an explanation of the striking and unusual anomaly which it presents. I was unable to find an exactly similar case in the literature of teratology.

The cases found in the literature which are to some extent analogous to the one about to be described are by Gurlt ('77), who gives an account of a calf embryo with a lateral prolapse of the abdominal viscera through the spinal column: Veraguth ('01) described a human embryo with ectopia of the spleen and intestines. Finally, in 1917, Williams described a calf with the omasum and spleen extruded from an opening in the occiput. In all these cases the spinal defect is in or near the cervical region, while in the calf here described the defect occurs in the lumbar region.

Unfortunately, the head and extremities of the specimen which I describe were removed before it was brought to the museum. The musculature was removed and only that part of the vertebral column and viscera shown in figure 1 remained. No clinical history of the case is available.

The specimen under consideration is a nearly mature calf foetus which exhibits two well-marked defects: 1) an extreme degree of spina bifida and, 2) a well-marked dorsal hernia.

The cleft in the spinal column is complete and involves the entire lumbar region. X-ray photographs show that the six

lumbar vertebrae are affected and that halves of these arch around both sides of the defect, producing a somewhat triangular vertebral fissure, 7 cm. long and 3 cm. wide at the cephalic end. However, the area of complete spina bifida extends for only 2 cm. from the cephalic end of the defect; caudal to this point merely the vertebral arches are separated.

The vertebrae are more or less fused, especially in the cephalic end of the defect, where a bony prominence on the ventral side of the specimen gives evidence of this fusion. The tip of the transverse process of the sixth lumbar vertebra on the left side

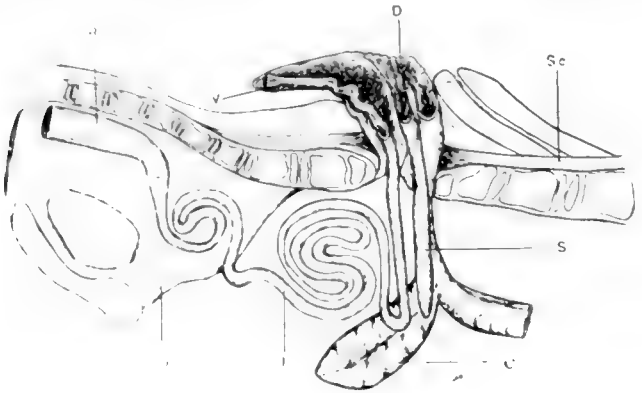

Fig. 1 Idealized sagittal section of foetus to show the relations of the intestines. *C*, caecum; *D*, dorsal opening of the intestinal pad; *I*, intestinal pad; *O*, os coxae; *R*, rectum; *S*, blind sac; *Sc*, spinal cord; *V*, ventral opening of intestinal pad.

lies under the innominate bone. The spinal cord is divided, the resulting halves passing around the defect. Nerves are given off on each side.

A pad of intestinal mucous membrane protrudes through the opening in the spinal column. When sectioned, this pad proved to be mucous membrane of the large intestine. Two openings in the mucous membrane, one dorsal and one somewhat ventral, communicate with the large intestine (fig. 1). The dorsal opening is the larger and communicates with a small portion of the large intestine posterior to the caecum and with a blind pouch which also proved to be a portion of the large intestine when

examined under the microscope. The remainder of the large intestine, that is, the portion extending from the anus to the pad, ends in a small opening on the ventral side of the caudal end of the pad.

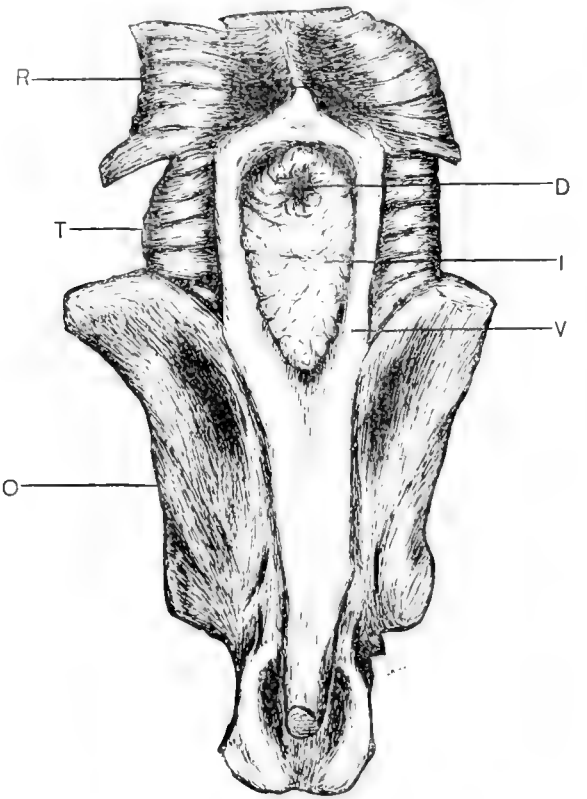

Fig. 2 Dorsal view of the defect, showing the relations of the intestinal pad. *D*, dorsal opening of the intestinal pad; *I*, intestinal pad; *O*, os coxae; *R*, rib; *T*, transverse process of lumbar vertebra; *V*, vertebral column.

The literature dealing with the causes of spina bifida is most extensive and the theories advanced are numerous. The theories of maternal impressions and amniotic adhesions need only be mentioned here. The first has long been discarded and the latter theory has also been looked upon as invalid. Gurlt ('77),

in assigning a cause for the condition which he describes, mentions the adhesions of the membranes caused by tearing due to turning of the foetus. This is a rather vague explanation at best. Modern investigators would more likely agree with Mall, who says: "Since monsters are produced in animals without an amnion, it would be well, it seems to me, to relegate the amniotic theory of the production of monsters into the class into which that of maternal impressions has fallen."

Of more importance, it seems to me, are the theories which regard a disturbance of growth metabolism as the causative factor in producing abnormalities. The experiments of Hertwig, Morgan, Stockard, and others may be briefly mentioned.

In 1892 Hertwig published his classical essay on "Urmund und Spina Bifida," in which he showed that spina bifida could be produced by the action of morphine. Morgan, in 1894, produced spina bifida by adding 0.6 per cent sodium chloride to the water in which eggs were developing. Hertwig, in 1896, found that salt solutions stronger than 0.6 per cent retarded development and the eggs died without going beyond the gastrula stage. Similar results were obtained by Hertwig and Morgan by raising the temperature of the water.

Godlewski ('97, '00, '01) and Samassa ('96, '98) found that spina bifida could be produced through lack of oxygen. This might easily be the case in faulty implantation.

Baldwin ('15) was able to produce spina bifida in almost every instance by treating the yolk portion of the egg with violet rays. The action of the ultra rays, by destroying a portion of the yolk hemisphere, results in an upset of the balance between the differentiation of the neural canal and the approximation of the blastoporic lips. The differentiation is not retarded, and the half tubes differentiate into two tubes before the lips of the blastopore close.

In the present instance, the defect unquestionably arose very early in the development of the individual and is essentially the same as those produced by Hertwig, in whose experiments spina bifida or 'ring' embryos resulted from incomplete approximation of the blastoporic lips.

There is no evidence that gastrulation in the calf is accomplished by means of blastoporic lips, but we may regard the primitive streak as homologous with the blastoporic lips, since both give rise to spinal cord, notochord, and mesoderm. The opening, in this instance, may be a secondary condition which has arisen in the region of the potential neurenteric canal, the persistence of which has been recorded in numerous instances.

The failure of the blastoporic lips (primitive streak) to approximate closely, differentiation, however, not being retarded, results in an opening bounded by material which becomes spinal cord, notochord, mesoderm, and perhaps a small amount of entoderm. In any case, however, the latter would adhere to the edges of the opening forming a passageway into the primitive digestive cavity which may or may not coincide with the position of the potential neurenteric canal. Veraguth ('01) regards the open neurenteric canal as the cause of the anomaly which he describes.

The dorsal hernia which occurs in this specimen may be interpreted thus: There is a gap in the dorsal wall of the intestine at the primitive streak, and the ventral wall pushing up through the gap has produced a pad of mucous membrane such as here found. I regard the blind sac as an outpocketing caused by a fold in the intestinal wall. The steps in the formation of this dorsal hernia may be easily understood by consulting a series of figures given by Cullen in "The Umbilicus and its Diseases," page 224.

It is interesting to note that spina bifida always occurs high up or low down in the spinal axis and to speculate why the defect should be so restricted. Lebedeff's ('81) theory that the curvatures of the spinal axis disturb the normal development of the medullary tube seems to be invalidated by two facts: 1) the neural folds have already closed before the body acquires its normal curvatures and, 2) the cervical flexure is most pronounced, whereas spina bifida is most frequent in the lumbar region.

In conclusion, I wish to thank Professor B. F. Kingsbury for many helpful suggestions; Professor W. L. Williams, who loaned the specimen for description, and Mr. R. R. Humphrey, who made the drawings.

Resumen por el autor, R. M. Strong.
Escuela de Medicina de la Universidad Loyola, Chicago.

Sobre un modelo económico de los principales tractos de la médula espinal y tallo cerebral.

Este modelo incluye dibujos de secciones transversales (aumentadas ocho diámetros) practicadas en cuatro niveles de la médula y en siete niveles del eje cerebral, montadas sobre un tablero de diez piés de longitud y un pié de anchura. Para representar los tractos mas importantes se emplean cintas coloreadas. El problema de indicar el trayecto de los tractos entre el tallo cerebral y el cerebelo se resolvió colocando un arco sobre la región del puente. En este arco se insertan los tractos con conexiones cerebelosas, representados por cordones colorcados. Los materiales empleados en este modelo suponen un gasto mínimo. Este modelo ha sido usado con gran provecho por varias clases, siendo especialmente útil para la obtención de conceptos sobre la proyección de los tractos.

AN INEXPENSIVE MODEL OF THE PRINCIPAL SPINAL CORD AND BRAIN STEM TRACTS

R. M. STRONG

Department of Anatomy, Loyola University School of Medicine

TWO FIGURES

The apparatus described here has been useful in helping my students in the difficult work of learning the tracts of the cord and the brain stem. It is especially helpful in getting projection conceptions, and it involves little expense.

Drawings with a magnification of eight diameters were made for four levels of the cord and seven levels of the brain stem, the last being through the diencephalon. These drawings were made on light bond typewriter paper, and they were pasted on light binding board to produce what will be termed sections in this paper. In order to have the structure outlined visible on both faces of each section, a reverse copy of each drawing was made. This was accomplished by tracing the second drawing for each section on a piece of paper which was held against the back of the sheet of paper bearing the drawing. The two sheets were placed against a window pane with the first drawing against the glass. With sunlight transmitted through the two sheets, it was easy to make the tracing.

The pictures can of course be made by photography or with the aid of a projection outfit. A pantograph can also be used to advantage in getting a desirable size for the drawings.

A board 10 feet long and 12 inches wide was used as a base; it was stained and varnished. The sections were mounted on the board by means of strips of galvanized sheet iron (figs. 1 and 2) These strips were cut $1\frac{1}{2}$ inches wide by $4\frac{1}{2}$ inches long. Each strip was bent so that two limbs making a right angle with each other resulted. One of these limbs, $3\frac{1}{4}$ inches long, was fastened

to the board by screws. The other limb, 1¼ inches high, has a vertical position. Two pairs were used for each section, and they were mounted so that the vertical limbs had just enough space between them to insert the base of a section with a tight fit.

Before mounting, holes were made in the horizontal limbs for the screws used in fastening them to the board. It was not found necessary to fasten the vertical limbs to the sections as the tight fit and the strings employed in the model hold the sections in place.

There is a tendency for the sections to be pulled away from a vertical position by the taut strings. This difficulty was met by using a piece of white string as a stay line. It was attached to the top of each section at its middle and was tied at the ends of the board, after being made taut.

Colored strings were used to indicate tracts, and they were fastened at their ends to nails. A tract not extending the whole length of the cord, for instance, is represented by a string which was deflected beyond its last level in the model to a nail at one side.

Descending tracts are represented by red strings, exteroceptive by blue, proprioceptive by yellow, and association tracts by purple. The colors fade eventually and become dull from soiling, in which case it is a very simple process to substitute new strings for the old. The regions occupied by the tracts are indicated diagrammatically with corresponding colors in the drawings.

The cerebellum presented a perplexing problem in constructing the model. This was finally solved by placing an arch as seen in figure 1 over the pons region. Tracts passing through the restiform body, brachium pontis, and brachium conjunctivum are represented by strings which have the cerebellar ends attached at the top of the arch.

Decussations are represented in the drawings by the usual methods (fig. 2). In the case of the strings, the problem was solved by passing the string across the face of a section in the region of the decussation in question. The section is perforated three times by each string in such cases instead of once. The

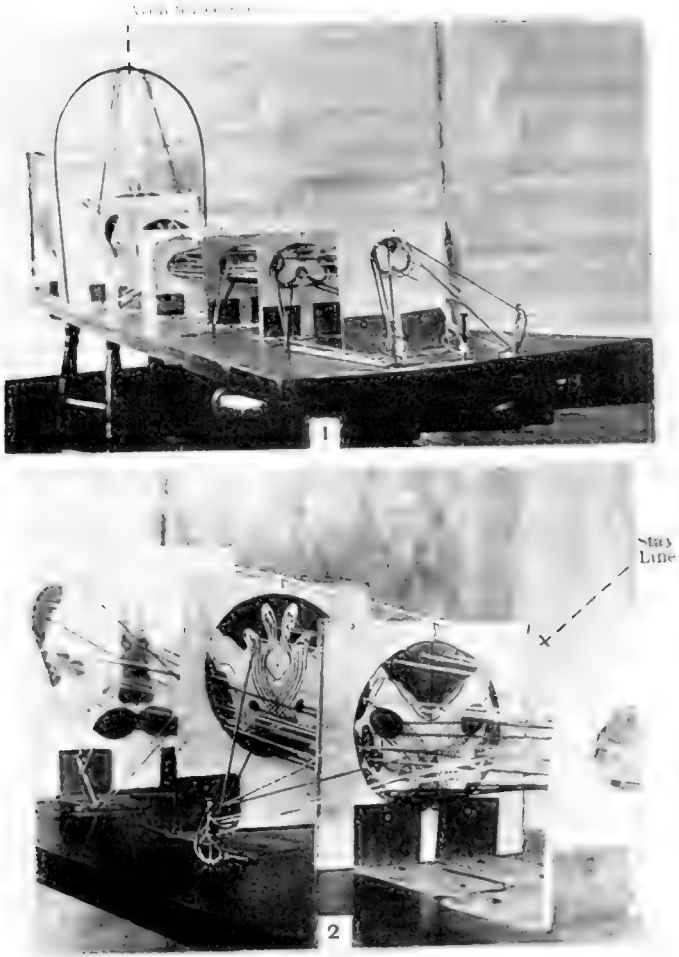

Fig. 1 View of entire model
Fig. 2 View showing region of fillet and pyramid decussations

string goes through the section before decussation back again through a second aperture and then a third time through after decussation. The same procedure was followed for the string representing the tract of the other side, and the two strings cross each other in the median plane.

Apertures in the sections were made with a steel punch before mounting on the base board. The strings were passed through the apertures with the aid of a large darning needle.

This model is large enough to permit a number of students to study it simultaneously and it is in almost constant use during laboratory periods. I have not labeled any part of it, as I prefer to have the students identify the structures represented. A limited amount of assistance in interpreting the model is given.

Resumen por el autor, Jacob Reighard.
Departamento de Zoología, Universidad de Michigan.

El almacenamiento y manejo de cuadros murales.

En vez de los listones de madera que se usan ordinariamente, el autor emplea listones de madera "basswood" teñidos con creosota. Las dimensiones de estos listones son $\frac{1}{4}$ de pulgada de espesor por $\frac{1}{2}$ de pulgada de anchura. Se clavan estos listones a los cuadros empleando clavos de alambre de $\frac{1}{2}$ pulgada de diámetro, y debajo de las cabezas de dichos clavos se perforan cuadrados de hierro galvanizado del num; 28. Los listones ocupan la superficie anterior de cada cuadro y los clavos se clavan en los lados libres. Cada listón superior lleva un gancho Hodge atornillado en el centro del listón. Cuando se hace girar al gancho de modo que venga a coincidir con el plano de la lámina, sirve para colgar esta última de una barra de hierro colocada en el cuarto en donde se guarden las láminas. De este modo éstas se conservan sin arrugas, y puesto que los listones ocupan muy poco espacio, pueden colgarse todas ellas de un modo semejante al de las hojas de un libro suspendido por el lomo. Las láminas se arreglan en orden de materias por medio de números, como si se tratase de un catálogo de materias, y cualquiera de ellas puede fácilmente sacarse y volverla a su sitio. Cuando se necesita usar una de las láminas se hace girar el gancho 90 grados, y entonces puede colgarse de un bastidor, alambre o cualquier otro soporte en la clase. Algunos de los mecanismos descritos han venido usándose hace largo tiempo; otros son nuevos. Sirven para coleccionar láminas de todos los tamaños en un espacio mínimo y para poderlas guardar en orden y emplearlas invirtiendo el menor tiempo posible. El presente trabajo indica donde pueden obtenerse los materiales empleados y su coste.

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED
BY THE BIBLIOGRAPHIC SERVICE, MAY 10

THE STORAGE AND HANDLING OF WALL CHARTS

JACOB REIGHARD

Department of Zoology, University of Michigan

FOUR FIGURES

The maker usually supplies charts with wood rods tacked and glued to the ends. In use they are hung from hooks on the wall of the lecture room by means of two metal rings tacked to the upper rod. When stored they are rolled and tied about with tapes. In the Zoology Laboratory of the University of Michigan we have tried probably every known device for the storage of rolled charts. They may be piled on racks such as once were used at Harvard University. To make these, pieces of round iron, some 30 inches long or more, are bent for a couple of inches at the ends, flattened and drilled at the middle, and screwed horizontally to wooden uprights to as to project on both sides like large coat hooks and form two ladder-like sets of supports. On two such uprights, properly spaced, one may store many charts and classify them roughly. The uprights may be built on a base with casters beneath it and the whole contrivance wheeled from place to place. Labels may be written on discs of cardboard tacked to the ends of the chart rollers. As the charts accumulate and are piled several deep on each support, it is impossible to keep them in order and much time is wasted in locating and reading the small labels. In spite of the most ingenious labeling it is often necessary to unroll the charts to find those that are suitable, and this entails not only loss of time, but damage to the charts.

To find the charts more readily, we have tried supporting them on pairs of large iron hooks screwed into vertical wood strips nailed to the walls of the lecture room. The charts then lie in one plane like the rungs of numerous ladders set against the wall. They may be classified and labels put beneath the groups. But

as the collection grows it takes much wall space. It may become necessary to climb to reach the uppermost charts and they have still to be unrolled.

In place of supporting the rolled charts on metal rods, one may use deep wood frames divided into compartments like the boxes in a post office. These may be arranged to hold the charts in vertical or horizontal position, but we have found this plan as cumbersome and wasteful of time as the other.

Home-made charts accumulate in every laboratory and are apt to be of various sizes and of material that deteriorates if kept rolled and frequently unrolled. To avoid the labor of attaching them to rollers, one is tempted to let them lie flat, and we have piled them thus in large cases with numerous close-set shelves on which they may be roughly classified. It is not easy to label such charts so as to find readily what is wanted, and in pulling one from a pile for examination it is likely to be torn or damaged by rubbing. To return it to its proper place the whole pile must be taken out. Naturally one puts the chart back on top of its pile or on top of some other pile and the whole collection is thrown into confusion. In addition to this, if some charts are kept flat and others rolled, there are two places to look and time is wasted in the search.

In hanging the charts for use the two rings at the top must be put over hooks on the wall of the lecture room. To accommodate the unequal spacing of the suspension rings of different charts, the hooks must be movable. One may suspend picture hooks from a molding or wire and slip them along until the suspension rings of the chart will go over them and one must climb a ladder to do it. One may dispense with the ladder by using a wooden frame filled with wire netting and arranged to be raised and lowered by ropes and pulleys. The picture hooks may be stuck into the lowered netting at suitable intervals, the chart rings slipped over them, and the whole thing hoisted, or one may cover the hoistable frames with cotton cloth and pin or clip his charts to that.

After trying most of the plans outlined, we sought a means of keeping all charts in a minimum space in one collection with-

out rolling them and so that they could be classified and examined and each removed and returned without disturbing the rest. We sought also the easiest way of hanging them for use. The result combines the unpublished devices of friends with some of my own. The universities in which I have seen some of these devices in use are indicated in parenthesis. I do not know that any other consistent scheme has been described in print.

We now store all our charts together by hanging them from a piece of $\frac{5}{8}$-inch iron pipe supported from the ceiling by a wire and stayed by wire to the side wall (Wisconsin). They are in a small room reserved for the purpose. The charts hang flat, one against another, like the leaves of a book. Because the wooden rods take too much room, we have removed them and have substituted thin strips of basswood (fig. 4, chart at right.) A thousand of these $\frac{1}{4}$ x $\frac{3}{4}$ inches by 40 inches, cut at a planing mill, now costs $18.00. Probably any good soft wood would answer, but hardwood warps so that the strips do not stay flat. The strips are stained brown by dipping in creosote. They are tacked to the face of the chart along its ends by means of $\frac{1}{2}$-inch wire tacks or clout-nails set from 4 to 6 inches apart and clinched on the free face of the strips. To keep the heads of the nails from tearing through the charts we have put under each a piece of 28-gauge galvanized iron. This is $\frac{1}{2}$ inch square, perforated at the center, and has the corners turned with pliers to as to form small points that penetrate the chart and go a little way into the wood. We find it better not to use glue, and none of our charts attached to the strips by tacks in the manner described has yet come loose from its supports. A piece of sheet iron 2 x 2 feet now costs fifty cents, and from it about 1000 squares can be made in the laboratory.

For suspending the charts we use the hook devised by Prof. C. F. Hodge. It is screwed into the upper strip at such a point as to make the chart hang level. When the hook is turned into the plane of the chart it serves to suspend it from its support in the chart room as a suit of clothes is hung from a rail (fig. 1). When the chart is to be used, the hook is turned through 90 degrees and may then be slipped over a picture molding, wire, or other

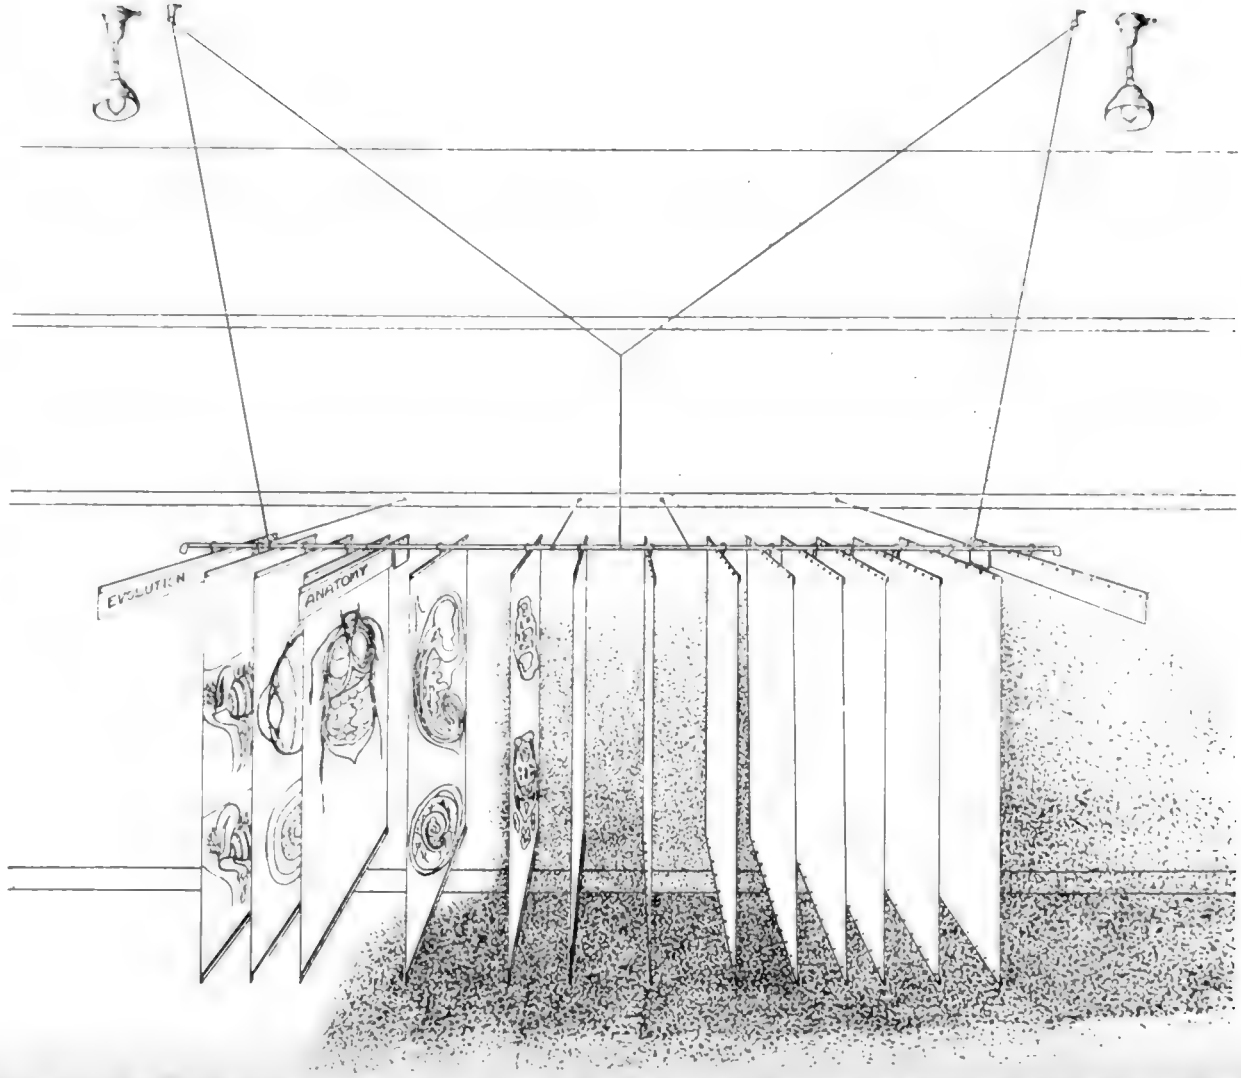

Fig. 1 Showing charts hung from an iron pipe in the chart room. The pipe is suspended from the ceiling and staxed to the wall by wire. Each chart is hung by a single Hodge hook.

support in the lecture room. To hoist it into place and get it down again, we use a light wood pole 6½ feet long, also Professor Hodge's device. At one end the pole is provided with a ferrule through which is driven the sharpened end of a piece of ⅜-inch round-iron. This is bent as shown in figure 3 and has its free end slotted to form a pair of claws like those on a tack-hammer. The hump on the suspension hook fits between the

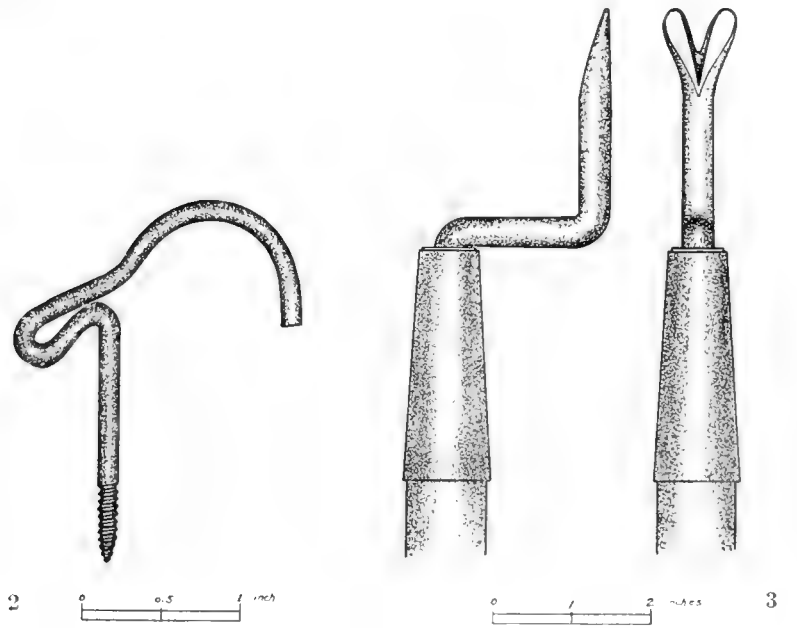

Fig. 2 The Hodge hook. See text
Fig. 3 Pole for putting up and taking down charts. For description, see text

claws on the pole and permits the chart to be handled without waste of time. In each lecture room a short suspension rod is provided. To this the charts are transferred after use and from it an assistant collects them from time to time and returns them to the chart room. The Hodge hooks were obtained from the Wire Goods Co., Worcester, Massachusetts, and cost, before the war, $1.35 per gross. The iron claw may be made by any blacksmith.

For displaying charts in the lecture room we have used a modified form of a device made for displaying buggy robes, and used for charts at the University of Wisconsin. As used by us, this device consists of eighteen wood arms, each supported by an iron rod, and arranged to swing like the arm of a derrick (fig. 4). The arms are pivoted to steel sectors which turn on the central upright axis. By turning the sectors all the arms may be thrown either to right or left. Each arm supports two charts back to back. Any one of these may be brought into view by turning the arms as one turns the leaves of a book held vertically. The device may be attached to the wall, as ours is, or carried on a movable base resting on the floor. It may be obtained from John Best, Galva, Illinois, and cost (in 1915) $19.00.

The whole arrangement has proved very satisfactory. The charts are designated by the numbers of the Concilium Bibliographicum gummed to the upper wood strip (fig. 4). They are arranged on the rail in systematic order, and any one may be located, removed, inspected, and returned to its place without difficulty. To subdivide them, index labels are hung at intervals (fig. 1). These are wood strips suspended from the rail by Hodge hooks. They project beyond the charts at one end and each bears at that end a square of chart cloth with an appropriate label and at the opposite end a thin bag of sand to balance it. Charts of any ordinary size may be accommodated. Very large maps may have to be kept rolled in a separate place, but they may be represented in the chart collection by appropriate dummies on which are written references to their location and to which may be attached photographs of them. Our collection consists now of 310 charts varying in size from 2 x 2 feet to $5\frac{1}{2}$ x 3 feet and made of various materials. These occupy in storage a space 11 feet long, but the same space will probably accommodate nearly twice as many and still permit anyone to be examined in situ. If longer hooks were used the charts could be hung alternately high and low from parallel supports so that the wood strips would not be opposite. The same space would then accommodate many more.

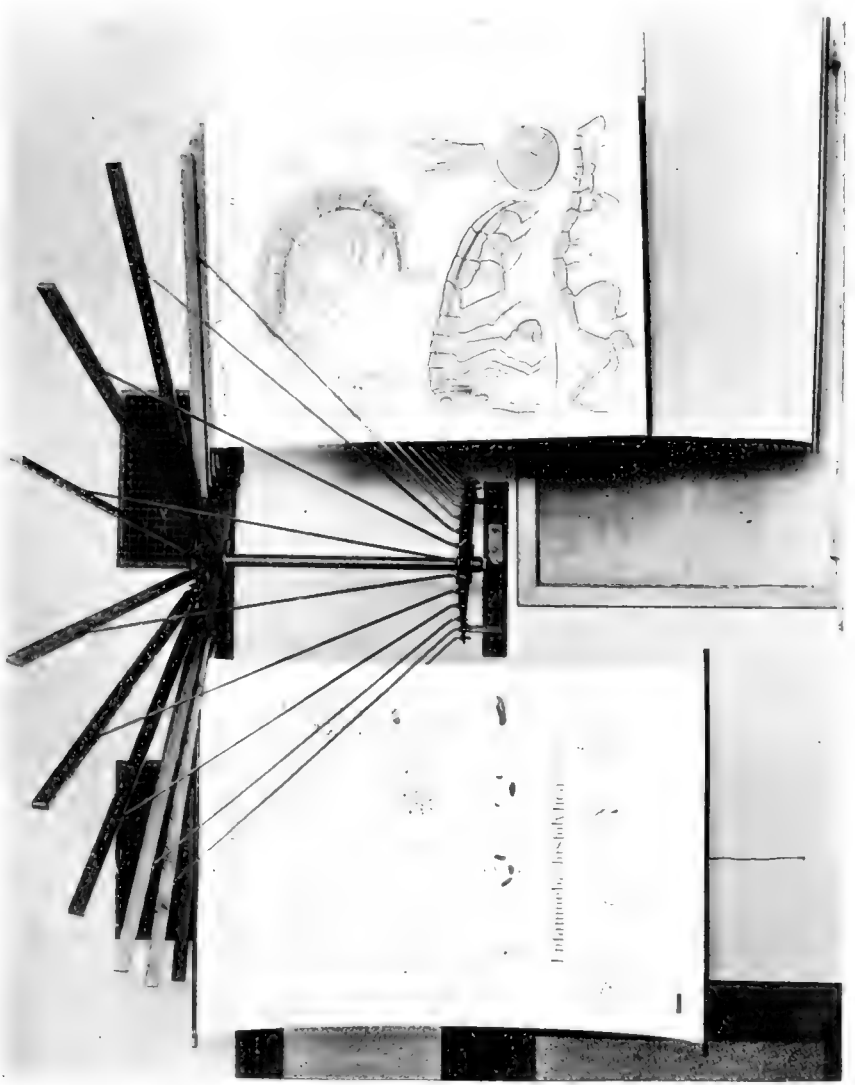

Fig. 1 The Best chart hanger for thirty-six charts, see text. The smaller chart at the right shows the basswood strips. The other two have the usual wood rollers. Note the place numbers on the upper strip.

As our collection grows we shall make a card catalogue of the charts in which each chart will be represented by small photographs (Pennsylvania). By attaching concilium numbers to the duplicate photographs and arranging them according to the concilium system, cross references will be made to many of the charts. Thus the chart shown at the right in figure 4 would be represented in the catalogue by several photographic cards, each of which would bear an identical number to show the location of the charts in the collection. These cards would bear also distinctive concilium numbers by which they would be placed in the catalogue under crustacea, embryology, and under one or more anatomical designations.

Resumen por el autor, Roy Lee Moodie,
Departamento de Anatomía, Universidad de Illinois.

La naturaleza del sistema Haversiano primitivo.

Los huesos mas antiguos, encontrados en el Silúrico y el Devónico, carecen de verdaderos sistemas Haversianos, que se desarrollan primeramente con cierta extensión en Dinichthys, del Devónico. En este pez acorazado alcanzan el máximo de desarrollo en conexión con el proceso dentario de la maxila y premaxila. Las lagunas participan de la naturaleza de los odontoblastos; los canalículos nunca comunican entre sí; la laminilla fibrilar existe; las fibras perforantes no se han desarrollado; el canal central es ancho. El polariscopio es útil para distinguir la naturaleza de los sistemas Haverísanos primitivos. No existen pruebas sobre la evolución de la estructura del hueso; se percibe un cambio bastante brusco con la introducción de las formas de mamíferos.

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED
BY THE BIBLIOGRAPHIC SERVICE, MAY 10

THE NATURE OF THE PRIMITIVE HAVERSIAN SYSTEM

ROY L. MOODIE

Department of Anatomy, University of Illinois, Chicago

ONE PLATE (THREE FIGURES)

The term Haversian system is necessarily of very general significance and is used in a broad way to distinguish any concentric arrangement of osseous lamellae around a central canal. It is often difficult to distinguish between a dentinal system, that is, a concentric arrangement of dentine, around a dentinal tubule and a true Haversian system as seen in long bones, since the two often grade into one another. The presence of lacunae does not seem to be essential to an Haversian system, though they usually are present. In the fishes, both modern and ancient, osteoid tissue, largely lacking lacunae, may arrange itself around a vascular opening and thus have all the appearances of an Haversian system, and give the same orthorhombic light reactions under polarized light.

The type of such a system may be taken as those most highly specialized Haversian arrangements seen in the long bones of man, especially in the femur. From this complete system down to a slight lamellar arrangement of substances one may find all gradations in a series of fossil bones representing the history of the vertebrates from the Devonian to the Pleistocene. Such a review has been made, and it will doubtless be of interest to describe and illustrate the most ancient Haversian system of which we have any knowledge.

There is no apparent indication of a gradual evolution in form of the Haversian system from the most ancient vertebrates to modern mammals, although there is a gradual development in the form of the lacunae and canaliculi. The reptiles do not

show a higher type of Haversian system than do the amphibians or fishes, as they do in their skeletal organization. Haversian systems in dinosaurs are as primitive as they are in Devonian fishes. They seem to have sprung into existence full formed without undergoing the process of evolution such as has obtained in the bodily organization of the vertebrates.

The most ancient organization of osseous elements which simulate an Haversian system are to be found in the dental process of the premaxilla of a Devonian arthrodire, Dinichthys (figs. A and B), allied by some paleontologists with the lung fishes. This arrangement is well known to paleontologists and has been described by Claypole (94). These curious structures are not present in other portions of the armor of Dinichthys and are to be regarded as specialized dentinal systems, though not found in the true teeth which are not connected with the cranial skeleton. The Haversian canal resembles a dentinal tubule, the the lacunae are those seen in the cementum of modern fishes, the lamellae are fibrillar and partake of the characteristics of dentine as seen in the teeth (fig. C) of Carboniferous sharks, the interlamellar space is filled with cement and there are true interstitial lamellae, though never any of the type due to the partial absorption of other Haversian systems. I have not seen this type, known as false interstitial lamellae in any fossil vertebrate. The orthorhombic light reaction under polarized light is exactly like that of the highly specialized Haversian systems in the femur of man. The canaliculi from the lacunae communicate neither with each other nor with the central canal, nor do they do so in any fossil vertebrate below the mammals. The lacunae are not confined largely to the interlamellar spaces, as they are in mammals, nor is there any apparent plan in their arrangement. Often, as in a Permian reptile, one finds three lacunae grouped together, surrounded on all sides by wide areas of osteoid tissue lacking lacunae.

The use of polarized light is essential to an adequate understanding of the structure of fossil bone, since usually under polarization, lamellae, fibrillae, canaliculi, and other minute histological units, invisible under ordinary light, stand out with

startling distinctness. The importance of this has been commented upon by various authors in their studies on the histology of fossil structures.

Arey ('19) has recently called attention to the presence of Haversian systems in the membrane bones of man. The systems he described and figured, however, cannot be called true Haversian systems, but resemble those seen in fossil reptiles. It is interesting to note in the temporal bone of an Oligocene mammal an arrangement of substances exactly similar to those described by Arey for man. These intermediate or pseudo-Haversian systems often fail to give an orthorhombic light reaction, as they do in the case of the Oligocene mammal. The difference between the true and the intermediate types of systems is to be found in the absence of intercommunications of the canaliculi with either the central canal or other lacunae and in the occasional failure to secure the same light reactions. In all other respects they are similar.

The review was undertaken with the idea of gaining a conception of tissue organization in ancient vertebrates so that I might judge as to the disturbing effects of pathological processes upon the structure of the part. The presence of osteoid tissue in ancient vertebrates is a normal condition. Kolliker ('57) noted that many fish bones are composed entirely of osteoid tissue. One interesting effect in pathological conditions of fossil bone is to stimulate the growth of pseudo-Haversian systems, and to increase the vascularity of the bone. The same fact has been noted by Foote ('16) in the fractured femur of a frog, where Haversian systems are ordinarily absent.

SUMMARY

Primitive Haversian systems of the very ancient vertebrates differ but slightly from highly developed systems of modern mammals and have been but slightly modified by the passage of time. Each group of vertebrates has its own type of lacunae, but the organization of the Haversian systems remains the same. The concentric arrangement of lamellae is not an incident of

evolution, but a response to the mechanical laws of organization of the part. True Haversian systems are confined to the mammals.

A more complete account and more adequate illustrations will be found in the Williston Memorial Volume now in preparation.

Resumen por el autor, Hubert Sheppard,
Departamento de Anatomía, Universidad de Kansas.

Hermafroditismo en el Hombre.

En el hombre, el hermafroditismo con existencia de testículos y ovarios normalmente desarrollados en el mismo individuo aparece raras veces. En el individuo descrito en el presente trabajo los testículos aparecían en el escroto y los ovarios en la cavidad pélvica. El tejido que formaba ambos órganos era normal en estructura en todos sus detalles. Se podía distinguir perfectamente una pared muscular uterina que limitaba una cavidad que desembocaba en la vagina. Las túnicas del conducto deferente y el oviducto, así como sus cavidades podían también distinguirse. El cuello del útero ocupaba casi exactamente la posición del utrículo prostático del varón. En todos los casos de hermafroditismo se ha podido comprobar una distinción marcada entre los tejidos genitales masculino y femenino, sin encontrarse nunca una mezcla indefinida de ambos elementos (es decir, un verdadero ovotestículo). En el raro caso descrito encontramos el mismo fenómeno con una separación aun mayor de las dos clases de tejido, puesto que los testículos y ovarios ocupaban su posición normal correspondiente.

HERMAPHRODITISM IN MAN

HUBERT SHEPPARD

Department of Anatomy, The University of Kansas

SEVEN FIGURES

An opportunity to make a study of the anatomical structures of the genital organs of hermaphroditism in man is seldom found for two reasons: first, such irregularities seldom occur and, second, when they do occur the material is exceedingly difficult to obtain for laboratory purposes. As recently as 1911 it was asserted that "hermaphroditism in the sense that separate testicles and ovaries are found has not been demonstrated in man, nor even in other mammals beyond a doubt." We thought it worth while, in the light of this and other investigations, to report a study of the anatomical structures of an extreme case of hermaphroditism which came to the dissecting room. The gross study is supplemented by microscopical examinations in so far as the condition of the material would permit.

The cadaver featured, objectively, both as a male and as a female subject. Hair was lacking on the face and scant around the genitals, the body was large and obese, with the mammae well developed, large and flabby, which in every way resembled a female rather than a male organ. One would have judged, in so far as the external genitals were concerned, that they were male rather than female genitalia. However, upon a closer examination, one could see that there were certain irregularities. The penis was small with a dilated urethral orifice three-fourths as large as the organ itself (fig. 1). The scrotum appeared to be abnormally large, although the testicles, upon palpation, were found to be normal and symmetrically formed. When the region posterior and beneath the scrotum was palpated, its apparent unusual size was found to be due to a large fold or ridge which extended from near the anus to the pubis on either side of the penis.

THE FEMALE EXTERNAL GENITALIA

After the skin and scrotum were completely reflected from the urogenital triangle, the large ridge beneath the scrotum was found to be a structure which resembled female external genitalia. Both the labia majora and minora were nearly normal in size, the former extending to the posterior commissure, while the latter formed the frenulum. The skin and dartos of the scrotum divided into two lamina on reaching the postero-inferior part of the labia majora. The superficial layer continued as the skin and fascia of the femoral region, the inner lamina thickened into the labia majora. The minora was two membranous folds within the majora and surrounding the penis or enlarged glans clitoris. At this stage of the dissection, if one would disregard the latter enlarged organ, the cadaver was nearer a female than a male subject.

THE PENIS AND VAGINA

The penis in all respects resembled a glans clitoris which had developed into an organ that closely figured externally as male genitalia with a cone-shaped dilated urethra (fig. 1). At the large or vaginal end of the urethra was an opening that extended back into the uterus through the prostatic-cervix of the uterus (fig. 2), which will be described later. The penis was small, measuring a little more than $1\frac{1}{2}$ inch in length and $\frac{1}{2}$ inch in diameter. The glans had a prepuce fused with the erectile tissue of the corpus cavernosum, and was only a rudimentary fold at the end of the organ. The dorsal vein, arteries, and nerves were regular and similarly related as those found in a normal subject. Externally, the urethral orifice of the corpus cavernosum urethra (fig. 1), measured $\frac{3}{8}$ inch in diameter. This opening gradually increased in diameter until it was a little more than an inch in diameter at the urogenital diaphragm. In so far as we could note, there was no spongiosum tissue present in the urethral part of the organ. Both the urethra and the vagina opened into this enlarged urethra. The true urethra

itself was only about $\frac{3}{4}$ inch in length. This duct passed through the upper part of the prostatic-cervix portion of the uterus, while the vagina was located in the lower two-thirds and extended upward and backward into the uterus proper. Posteriorly, the corpus cavernosum penis divided into two short crura (fig. 1) $\frac{3}{4}$ inch in length.

THE UTERUS

The body of the uterus was separated from the bladder by the vesico-uterine fold of peritoneum in the usual manner. However, the uterus as a whole was somewhat lower down in the pelvic cavity than is ordinarily found in normal cases. This was due possibly to the development of the organs—the fusing of one genital system with the other. The greatest width of the uterus was 1.5 cm., with a total length of 5.5 cm.; the body was 4 cm., and the prostatico-cervix 1.5 cm. A uterine body cavity was perfectly developed, and measured nearly 5 cm. This cavity extended into the uterus with little demarcation between the two organs. The entire cervix was fused with the prostate; in fact, the prostate was a mere enlargement of the cervix of the inferior extremity of the uterus. The uterus held the same relation to the prostate that utriculus prostaticus holds in a normal male subject. Not only the lumen, but the uterine glands and muscular walls could be easily defined (fig. 3). The ductus deferens entered the prostatico-uterine canal of the cervix by piercing its posterior wall (fig 2). A broad ligament was well developed, resembling in every detail a normal female subject except the course of the ductus deferens, which will be described later, and it was a little thicker and wider, due to the fact the uterus was a little lower in the pelvis as has been previously described.

THE DUCTUS DEFERENS

The ductus (vas) deferens differed in no respect from a normal male subject until it passed through the annulus inguinalis abdominis in connection with a very rudimentary ligamentum teres uteri (fig. 2). It then coursed alongside, and posterolateral

to the oviduct, at first encircling the ovaries. When it reached the level of the uterus, it made a quick S-shaped turn, and entered the superior part of the cervix of the prostatico-uterus. The histological structures of the duct are very well developed. The epithelium surrounding the lumen is slightly disintegrated, as is shown by the photograph The circular and longitudinal muscle layers are clearly defined, and in a number of sections the tunica propria and the inner longitudinal layer are also easily recognized (fig. 4).

THE OVARIES AND OVIDUCT

The ovaries measured about 1 inch in length and ½ inch in breadth. They were attached to the mesovarium in the usual way. However, the ovaries were found to be in a poor state of preservation for histological purposes; nevertheless, some of the materials stained sufficently well to demonstrate the ovarian tissue. One of the larger follicles as well as a number of smaller are shown in figure 5. A little below the folicles is a light area where the corpus luteum has disintegrated from the rest of the tissue.

Each oviduct took a normal course to the proximal opening into the uterus (fig. 2). The course of each duct was at first almost horizontal, lateral, and posterior from its attachment to the uterus until it reached an inferior lateral portion of the pelvic wall where it came into relation with the uterine extremity of the ovaries. Then it coursed at right angles, and passed almost vertically upward along the mesovarial border of the ovary to the mouth of the infundibulum and the fimbriated extremity of the duct. Microscopically, the sections of the oviduct very clearly differentiated the various tunics; the serosa, the longitudinal, and the circular muscle layers show with marked clearness (fig. 6). The epithelium as well as the inner part of the mucosa has somewhat disintegrated from the lumen. It was possible in many of the sections to define the epithelial cell structures. A lumen extended throughout the full extent of the duct.

THE TESTES

The testes did not differ from a normal testicle, except in size. The right testis measured $1\frac{1}{2}$ inch in length, $\frac{3}{4}$ inch in breadth and 1 inch in diameter anteriorposteriorly. The left testis was nearly the same size as the right except for length. It measured a little more than $1\frac{1}{4}$ inch. Each testis lay upon and slightly laterally to the large ridge or fold beneath the scrotum. This arrangement gave the scrotum its extremely large appearance when viewed in its normal state. The funiculus spermaticus had all of its usual structures, even the pampiniform plexus was easily worked out. A small round ligament, before mentioned, was fused with the funiculus as far as the point where the labia majora began. At this point it was lost and could not be traced any farther along the cord.

This tissue, like the ovaries, was in a poor state of preservation for histological study. However, in many of the sections the convoluted tubules could be easily differentiated (fig. 7). Only the shape of the tubule with its contents could be clearly defined. It was impossible to differentiate between sexual and sustentacular cells except in a few sections. In these better sections, a few interstitial cells could be observed under oil immersion.

DISCUSSION

According to Virchow, this individual subject would be an individuum uterusque generis, since both male and female organs are found almost equally developed. Klebs regards a hermaphroditismus verus as a subject who possesses both male and female genital organs united in it. In the specimen under consideration, we find two sets of reproductive glands. They were not united in the sense of ovitestes, but since both the ductus (vas) deferens and the oviduct (Fallopian tube) enter the uterus and, further, the round ligament and the spermatic funiculus have a union as well as a natural position and course, we can say that there was an indirect union. Even according to Kleb's definition this would be an hermaphroditismus verus.

Gudernatsch says that "hermaphroditism in the sense that separate testicles and ovaries are formed has not been demonstrated beyond doubt." Except for minor variations which we have previously described, we find not only separate testicles and ovaries which are in their normal position in the body, but also a complete male and female urogenital system with the exception of the urethro-vagina and the prostatico-cervix of the uterus. Here we have noted the fusion of the two systems into a single system where male and female are combined.

Such a finding as this substantiates the old theory of Waldeyer that there is a bisexual anlage of the genital ridge. We cannot quite see how Benda's theory, "that the primary anlage of the entire sexual system of the vertebrates must be regarded as female," would harmonize with facts now recorded. A separate development would seem to be further substantiated by the fact that in every case of hermaphroditism on record there is always a sharp distinction between the two kinds of tissue, and never an undifferentiated mixture of both elements, as would be the case if the germinal epithelium could produce either male or female reproductive tissue.

In every male subject the prostatic utriculus, a homologue of the vagina of the female, can be demonstrated. It would appear from what we know of the embryological development of the urogenital system that there would be a fusion of the prostate, vagina, and uterus in an hermaphroditismus verus. This would no doubt explain the variation or fusions of the two systems found in the cadaver we are considering.

EXPLANATION OF PLATES

All the figures are untouched photographs of the organs described in this paper. Figures 1 and 2 are macroscopic photographs of the external and internal genital systems. The remainder of the figures are microscopic photographs.

PLATE 1

EXPLANATION OF FIGURES

1 A photograph to show the external genital organs. The short penis has been dissected out with its crura and laid upon the pubis. The dilated urethra has been split and pinned open to show the small opening into the vagina as it turns backward to enter the uterus.

2 A photograph of the same section from a pelvic view. The vagina and uterus have been laid open and pinned backward to the broad ligament. The ductus deferens can be seen on the right side near the upper extremity as it enters the cervix of the uterus. Near the lower extremity of the uterus can be seen both oviducts coming off from the angle of the uterus. The bladder could not be shown in the photograph.

3 A microscopic section to show the lumen and muscular wall of a portion of the uterus. This was taken from the right side 2 cm. from the cornu.

1

3

2

PLATE 2

EXPLANATION OF FIGURES

4 A section of the ductus deferens to show the tunics. Considerable disintegration has taken place in the lumen. However, all the layers of the duct show clearly in the photograph.

5 A section of the ovary. A large follicle is seen near the top of the photograph. Two smaller follicles to the right can also be seen. Below and near the bottom of the photograph is a light area. This was an area of disintegrated corpus luteum.

6 A section of the oviduct taken about half-way between the ovary and the uterus.

7 A low-power section of the testicle, to show the convoluted tubules and the connective tissue among the tubules.

BOOK REVIEW

LE EMOPATIE. By Prof. Dott. Adolfo Ferrata della R. Università di Napoli. Vol. 1. Parte Generale, XVI and 1–482 pp., 21 colored lithographed plates and 8 text-figures. Milano: Società Editrice Libraria, 1918. Price, unbound, L.30.00.

This is one of the most interesting, complete, and usable books on morphological hematology ever published. It is the kind of book which unfortunately cannot be produced in this country, for no American publisher could furnish the splendid colored lithographed plates and probably no publisher in this country would publish such an extensive text on a subject which necessarily appeals to a small audience. The plates are of exceptionally high quality, and the figures are so arranged that the plates will prove very useful even for those who have difficulty with the Italian text.

The text matter is arranged very systematically, and each chapter is followed by a very extensive bibliography. Citations to literature and discussions of theories are so numerous that the book will be of great value as a reference work to anyone working in this field. It should be accessible to every laboratory in which there is an interest in hematology.

The book is far more than a compilation of the work of others, for there is a hardly a phase of the subject to which the author has not contributed by his own researches, the results of which have appeared in numerous previous publications. The work is really an extended résumé of Ferrata's own work and that of his students and collaborators, Di Guglielmo and Negreiros-Rinaldi. Of special value is the fact that it has been possible to include the results of most recent research in this field. It is thus the only place where one will find a summary of much of this work.

The chapter on technique, to which the first eighty-four pages are devoted, gives a very complete account of the modern methods of counting, haemoglobin estimation, fixation and staining of blood smears and of the blood-forming organs, with considerable space devoted to the methods of supravital staining of fresh blood and the making of permanent preparations of blood smears stained in this manner.

Part II, sixty-three pages and eleven plates, deals with the red blood-cells. The results of supravital staining, the maturation of the red corpuscle, and the pathological morphology of erythrocytes, including polychromatophilia, basophilic punctation, Howell-Jolly bodies, etc., are prominent features of this section. Sixteen pages are devoted

to the discussion of basophilic punctation. In regard to the origin of the basophilic granules it is to be noted that Ferrata has given up his former view that they are derived from the parachromatin of the nucleus. With Pappenheim and Askanazy he now agrees that they are of cytoplasmic origin. His general conclusion in regard to basophilic granulation is that it represents a phase of maturation of normal erythrocytes in certain periods of embryonic life; it is atypical for the adult, and morphologically it corresponds to the basophilic substance of the primitive lymphoid erythroblast. In the normal adult the erythrocyte passes through a polychromatophilic phase in order to reach its final acidophilic state, but in pathologic conditions of the adult 'conglobation' of the basophilic substance during the polychromatophilic stage gives origin to the basophilic granules. Clinically, basophilic granules appearing in more or less severe types of anemia indicate a return of the mechanism of maturation of the erythrocyte to an embryonic type. In this connection it must be remembered that Ferrata's previous researches have shown that a condition analogous to basophilic punctation is a normal phase during the maturation of the erythrocytes of early mammalian embryos.

Several plates are devoted to illustration of the maturation of the erythrocyte and megalocyte. The numerous exceptionally clear figures include all important stages in the differentiation of red cells from the 'hemocytoblast' (primitive progenitor of all the granular leucocytes and erythrocytes) to the fully matured non-nucleated orthochromatic erythrocyte. Ferrata and Negreiros-Rinaldi have been successful in recognizing the very earliest stages in the differentiation of the red-cell series in a cell-type which they have named 'proerythroblast.' This cell retains the nucleoli of the 'hemocytoblast' ('lymphoidocyte' of Pappenheim), but shows some slight differences in other respects. The chromatin network is somewhat coarser and the light spaces between the chromatin strands are more sharply defined. The cytoplasm is more homogeneous and more basophilic and does not show the spongy differentiation of the primitive stem-cell. This cell is inserted between the lymphoid hemoblast of Pappenheim and the stem-cell. For the megaloblast a similar stage is recognized—the promegaloblast.

Part III, pages 167 to 242, plates XI to XVI, deals with the leucocytes. In the evolution of the neutrophil leucocyte Ferrata distinguishes between the 'proneutrophilic myeloblast' and the 'neutrophilic promyelocyte.' Excepting for the presence of fine azurophilic granules in a basophilic cytoplasm, the former resembles the hemocytoblast in structure. In the neutrophilic promyelocyte the fine azurophilic granules are gradually replaced by neutrophil granules lying in an oxyphilic cytoplasm and the nucleus gradually assumes the coarser structure which is characteristic of the myelocyte. The proeosinophilic myeloblast contains very coarse azurophil granules and the eosinophilic promyelocyte eosinophil granules in addition. It should be pointed out here that most authors do not agree with Ferrata's assumption of

relationship between the character of the azurophil granulation and the further differentiation of the myeloblast, although it is generally conceded that the azurophil granulation of 'myeloid' cells differs from that of lymphocytes.

Part IV, forty-four pages and one plate, deals with the blood-platelets. Naturally a large portion of this chapter is devoted to the various theories on the origin of blood-platelets and to discussion of the extensive literature on the subject. The discussion is unusually complete for a book of this kind.

Ferrata derives blood-platelets from megakaryocytes, as originally discovered by Wright, and also from 'monocytoid' cells having azurophil granules arranged in small groups as in blood-platelets. These latter cells are found especially in the bone-marrow of the embryo.

Part V, pages 313 to 399, dealing with the hematopoietic tissues, is the most interesting and original section of the book. Due consideration of the connective tissue as a diffuse hematopoietic tissue is a decided and much-needed innovation. The 'hemohistioblast' (resting wandering cell of Maximow, clasmatocyte of Ranvier) of the connective tissue and the 'hemocytoblast' comprise a uniform anatomical system, identical in embryological origin and differential potentialities; they form the hematopoietic parenchyme in the widest sense of the word.

The specific hematopoietic tissues of the bone-marrow, lymph nodes, and spleen are discussed first, this portion of the chapter being altogether too brief in proportion to the space devoted to the diffuse hematopoietic tissue. The hemocytoblast, similar in structure to Pappenheim's lymphoidocyte, is the progenitor of all the bone-marrow cells, and a similar cell in 'lymphoblastic function' gives rise to the lymphocytes of lymph nodes and spleen. The monophyletic theory is, therefore, accepted by Ferrata, but not the extreme unitarianism of Weidenreich and Maximow, for Ferrata believes in functional dualism to the extent that fully differentiated lymphocytes are incapable of differentiating into granulocytes or erythrocytes. In the spleen pulp the myeloid function of the hemocytoblast is retained to a certain extent, which explains the limited production of myeloid cells in the pulp of the normal adult.

The section devoted to the 'hemohistioblastic,' or 'diffuse hematopoietic' (connective) tissue is of special interest. The colloidal dyes (Trypanblau, Pyrrholblau, Lithiumcarmine) are made use of for the purpose of determining the relationships of the cells of this tissue. The primitive cell of this tissue is the resting wandering cell (Maximow) derived from an amoeboid embryonic mesenchyme cell and giving rise to all the other types of cells of the connective tissue. These are divided into chromophobe (without dye granules) and chromophile (with dye granules) types. The latter include the resting wandering cells, fat cells, endothelial cells, and fibroblasts. The fibroblasts, on account of the character of their dye granules, are regarded as highly differentiated cells, while fat cells and endothelial cells are considered to be functional adaptations of the hemohistioblast (resting wandering cell). The chromophobe cells include plasma cells, mast cells, eosino-

phils, and lymphocytes, and they are also differentiated from the hemohistioblast which loses its capacity for storing colloidal dyes during their differentiation.

In the opinion of the reviewer, much remains to be proved before this classification of Ferrata's can be adopted. The whole structure is built up on the assumption that the reaction of the cells to the colloidal dyes is specific. Recent work of the reviewer[1] seems to indicate that the reaction is not specific, but that the behavior of cells toward colloidal dyes depends entirely on functional and environmental conditions. In other words, the presence or absence of dye granules is not sufficient to enable us to distinguish between hemohistioblasts and lymphocytes, or between monocytes of the tissues and large mononuclears of the blood.

Serious objection may also be offered to the view that the 'hemohistioblast' is always a more primitive cell than the lymphocyte, and that the lymphocyte (of normal circulating blood) is a differentiated mature cell incapable of being transformed to a granulocyte and incapable of reverting to a hemohistioblastic resting wandering cell. In this connection it is sufficient to refer to the recent work of Weill,[2] who has shown conclusively that lymphocytes, even those having the structure of small lymphocytes, are capable of differentiation into granulocytes. It is true that these observations were made on human and mammalian thymus, spleen, and mucosa of digestive tract, but until real or even functional differences between lymphocytes of the blood and those of the tissues have been demonstrated, they must be regarded as valid objections to Ferrata's theory.

Numerous objections to Ferrata's view of the relationship between resting wandering cells and lymphocytes could be offered, but this is not the place for the lengthy discussion which would be necessary. Many of these topics are considered again in the following section, where the literature is given due consideration.

Part VI, pages 400 to 460, deals with the morphogenesis of the cells of the blood. The first part of the section is concerned with the genesis of the blood-cells of the embryo. Various theories are considered, but emphasis is placed on the results of the author's own researches. Although space will not permit discussion of this chapter, the reviewer wishes to call special attention to Ferrata's own conclusions in regard to the relationship of the blood-cells. The first basophilic lymphoid blood-cells derived from the mesenchyme of the early embryo are not lymphocytes, but a special type of 'primitive transitory hemocyto-

blasts' which are all under erythroplastic function. For a time they all differentiate into promegaloblasts, megaloblasts, and megalocytes, the primitive red-cell generation of the early embryo. In the second phase, that of the hematopoietic activity of the liver, the mesenchyme cell (hemohistioblast) differentiates into a new type of primitive cell, the definitive hemocytoblast in myeloid function which in turn differentiates into erythrocytes, granulocytes, and megakaryocytes. This second hemocytoblast corresponds morphologically to the 'myeloblast' or stem-cell of the adult. In the third (fetal) phase, during which the lymphoid tissue appears, the mesenchymatous hemohistioblast gives rise to a hemocytoblast of lymphoid function which produces lymphocytes, although it is morphologically identical with the myeloid hemocytoblast. The different end-products are due to temporary functional differences only.

According to this scheme all the blood-cells are traced back to the fixed tissue cell, the hemohistioblast, the cell which stores colloidal dyes in the connective tissue of the adult. In the early embryo this cell differentiates into the primitive transitory hemocytoblast, and this in turn to the primitive red cells of the embryo (megalocytes), while in the adult, lymphoid and myeloid hemocytoblasts (functional differences only!) and monocytes are the products of its differentiation. The monocytes may also be derived from both the lymphoid and myeloid hemocytoblasts.

This scheme seems to harmonize the actual observed facts with both the unitarian and dualistic theories better than any other scheme which has been presented. A good part of this section of the book is devoted to discussion of the unitarian and dualistic theories and the last fifteen pages to the doctrine of Ferrata.

In part VII, pages 469 to 482, the author discusses the morphological significance of the cells of the blood and the hematological formula. The discussion of the significance of azurophil granulation is of special interest. Ferrata takes the stand that the presence of azurophil granulation in a myeloblastic lymphoid cell indicates beginning differentiation toward a granulocyte, which may be either an eosinophil or neutrophil granulocyte, according to the character of the azure granules. The azure granules are not transformed into the specific granules of the leucocytes, but are replaced by the latter. The presence of azurophil granulation in myeloid cells, therefore, indicates maturity and beginning differentiation and is of greater significance than the mere temporary secretory activity assumed by Pappenheim.

The reviewer has picked out only a few of the interesting and significant parts of the book for special mention. In closing he wishes to state that the book constitutes one of the most important recent additions to hematological literature. The statement on the title page that it is a "Trattato per medici e studenti" is somewhat misleading, for it is more than an ordinary text-book.

University of Minnesota.

Resumen por el autor, J. A. Pires De Lima, Instituto de Anatomía
de la Facultad de Medicina,
Oporto, Portugal.

Estudio de un feto cíclope de cabra, macho, procedente de Nova Goa (India Portuguesa).

El feto estudiado tenía un solo globo ocular con dos córneas y tres párpados, uno superior y dos inferiores. Ausencia completa de aparato nasal; labio superior terminado en punta roma y mandíbula prognata y recurvada hacia arriba. Cerebro chato y cráneo en gran parte lleno de un líquido seroso que se veia por transparencia a través del frontal. Ausencia de nervios olfativos y oculo-motores externos; un solo nervio óptico. Un solo frontal, dos parietales, dos inter-parietales, un solo maxilar y, por encima de él un hueso al cual llama el autor interzigomático. Una sola órbita. Agenesia del etmoides, de los cornetes, intermaxilares, palatinos, lacrimales, nasales y vómer. Tres de los incisivos ya en franca erupción. Se trata de un ciclocefaliano ciclocéfalo, según la clasificación de G. Saint Hilaire, y de un Cyclops arrhynchus según la nomenclatura de Gurlt. Se compara este caso con otros descritos por el mismo autor y por diversos teratologistas.

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED
BY THE BIBLIOGRAPHIC SERVICE, MAY 24

ANATOMY OF A FETUS OF A CYCLOPEAN GOAT

J. A. PIRES DE LIMA

Institute of Anatomy of the Faculty of Medicine of Oporto (Portugal)

SIX FIGURES

Prof. Froilano de Melo, of the School of Medicine and Surgery of Nova Goa (Portuguese India), sent me for study a monstrous fetus of a goat. It was received by the Museum on the 4th of January, 1919, immersed in alcohol.

The skin was covered with white hair, except at the upper part of the head, where there was an extensive area of black hair, stretching forward and encircling the eyelids, as well as the lips; besides, some small disseminated black spots. At the top of the head there were noticed three vortices of hair arranged in the form of a triangle.

The fetus was of the male sex, and kept the umbilical stump of the cord. Only the head was abnormal. On external inspection (fig. 1), the presence of a single median eye was noted, under which there was found a deep depression corresponding to the nasal apparatus, which was completely missing. The tongue protruded from the mouth and inclined to the left. Above it, in the median line, one noted the upper lip ending in a blunt point, and underneath, a voluminous mandible, prognatic and turned up.

The ocular globe of this monster was possessed of two corneae separated by a narrow light median zone. It was surrounded with three eyelids, an upper one with a free and convex border and two lower eyelids convex free at the borders and united in the median line. Only one conjunctiva connected the ocular globe to the deep faces of the three eyelids, in its reflexion forming conjunctival culs-de-sac, superior, inferior, and lateral, right and left. The palpebral cleft was 2 cm. wide and 1 cm. high.

Close to the corners of the eye there were found long lashes, and on the right one there were observed long hairs inserted above and below the eyelids. In the depression existing between the eye and the mouth, on the wrinkled skin, two vortices of hair on the median line were to be seen and two tufts of hair (tentacles) crowned the anterior part of the lips.

The head was flattened transversely. The following measurements were obtained:

	cm.
Maximum anteroposterior diameter	5
Maximum transverse diameter	4
Distance from the nape to the symphysis of the mentum	7.3
Length of each ear	5

The cephalic index 80.[1]

The remainder of the fetus presented the following measurements:

	cm.
Circumference of the neck	9
Length from the nape to the basis of the tail	25
Length of the tail	4
Perimeter behind the implantation of the thoracic members	22

This specimen did not possess behind the mandible the pyriform appendices called in Portuguese brincos (ear-rings), commonly seen in goats, representing an auditory appendage of the second branchial cleft.[2] After having studied the external morphology, the osseous skeleton was exposed. The upper surface of the skull (fig. 2) presents the form of a lozenge, to the angles of which the frontal, parietal, and occipital bones, respectively, correspond. The cranial vault presented a smooth surface, comprising the following bones: frontal (*F*) single; parietal (*P*, *P*) separated by the sutura interparietalis; squama occipitalis (*S O*); two interparietal bones (*I P*), and finally a rhombic Wormian

[1] According to Chauveau and Arloing (Traité d'Anatomie comparée des animaux domestiques, 5e éd., Paris, 1903), the cephalic index of the caprid family should vary between 55 and 63.

[2] Louis Blanc: Les pendeloques et le canal de Soyen (*Journal de l'Anatomie et de la Physiologie*, 1897).

J. A. Pires de Lima: Agenesia do Canal auditivo externo e atrofia da orelha (Annaes Scientificos da Faculdade de Medicina do Pôrto, vol. 2, no. 3, 1915).

bone (W), between the frontal and the parietal bones. All these bones were connected by well-defined sutures. On the superior part of the frontal bone there was found in the median line the

beginning of metopic suture. Below it one noticed a slight roundish protuberance, behind which and below a transverse depression was to be found (fig. 3, *d*). Perhaps this protuber-

ance represented the first stage of a pin for the implantation of a future horn.[3]

On the lateral face (fig. 3) were to be seen: the squama occipitalis (*S O*), the interparietal (*I P*), the parietal (*P*), the frontal (*F*), the squamosal (*S*), the mandibular (*m*), the maxillary (*M*), the zygomatic (*Z*) bones, and moreover, one which I call interzygomatic, and was to be found between the two zygomatic bones, stretching to the median part of the orbital floor (figs. 3 and 4, *Iz*).

As not the slightest vestiges of the nasal fossae were to be found, there was also complete absence of the following bones: ethmoid, turbinated, intermaxillary, palatine, lacrymal, nasal, and vomer. The incomplete ossification of the bones of the base of the skull did not permit me to study the sphenoid, occipital, auricular part of the temporal, as well as the pterygoid. The alveolar portion of the maxillary bones was still also cartilaginous

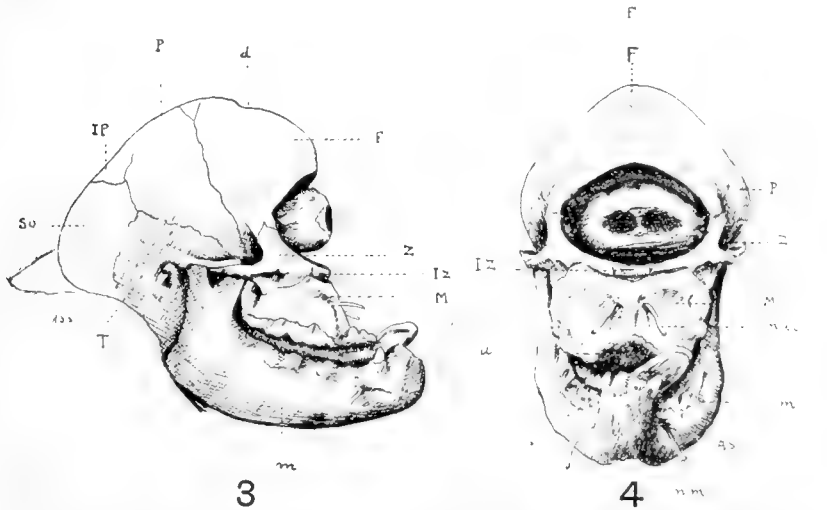
In figure 4 one observes the aspect of the skeleton of the head, seen from in front. One did not note any median sutures separating the maxillary bone and the symphysis of the mandibula was about changing into synosteosis.

The median and inferior parts of the single maxillary bone, not yet ossified, terminated in a reversed point (fig. 4, *a*). It was above this cartilaginous prolongation that the upper lip ending in a beak was to be found. Between the two zygomatic bones there was a median rectangular osseous segment, which I have termed the interzygomatic. The mandible (figs. 3 and 4, *m*), as we have seen, is extensive and protruding. On both sides of it the mentales nerves (*n m*) take exit. From the maxillary bone, close to the median line, the infra-orbital nerves (*n i o*) emerged. The orbit was ovoid in form and of median position, 25 mm. broad and 19 mm. high. The distance from the inferior border of the orbit (median line) to the part of the median prolongation of the maxillary bone was 15 mm.

[3] Plutarch says that a sheep with a single horn, very strong and solid in the middle of the front, was once brought to Pericles. Anaxagoras should have dissected the head of the animal and seen that its brain was pointed like an egg and its more pointed pole was in connection with the root of the horn.

The vault of the orbit was formed by the frontal bone, the lateral walls by the zygomatic bones and the floor, the ossification of which was incomplete, appeared to be formed by the zygomatic, interzygomatic, and perhaps the maxillary bones.

On removing the skull-cap, the brain was found to be reduced to a shapeless lamina of nervous tissue. The cerebellum appeared to be normal. The greater part of the cranial cavity, within the wide space, comprised between the dura mater and the upper face of the brain, reduced and flattened, was filled by fluid.



3 4

Concerning the cranial nerves, the following may be recorded: Of the olfactory nerves not the slightest vestiges were to be found; there was a single optic nerve, fasciculate, and in the median line (fig. 5, *II*); next in order the III, IV and V pair; the patheticus was thicker than the common oculomotor; there were no traces of the external oculomotor; the auditory formed a single fascicle on either side (*VII*, *VIII*); behind and within another fascicle represented the glossopharyngeal, the pneumogastric, and the spinal nerves (*IX*, *XI*) and a little behind and within that fascicle lay the great hypoglossal nerve.

After the dura mater had been taken away from the base of the skull, this presented the appearance reproduced in figure 6.

One notices in it from before to behind: the single optic nerve, on the median line, penetrating an optic foramen (*II*) as wide as the occipital one; a nerve (*III*, *IV*), which must represent the common oculomotorius and the pathetic nerve, distinct before the dura mater had been withdrawn; the n. trigeminus (*V*); the facial and auditory nerves (*VII*, *VIII*), and last all the following ones (*IX*- . . .) in a single fasciele. The hypoglossal nerve, which appeared well detached before the removal of the dura mater was not to be seen afterward.

The ocular globe was large, oval with a single optic nerve and a single cavity. Only the cornea showed signs of duplicity in the forepart. On opening the ocular globe, this was found so macerated as to make it unsuitable for study.

Contrary to what is generally the case, in this specimen,[4] which I suppose to be a dead-born fetus, three of the incisor teeth had already appeared: the pincer, the first right mitoyenne, single, as well as the first left mitoyenne, this being considerably developed. The left pincer and the second mitoyennes were beginning to appear.

The dissection of the neck and the autopsy of the thorax and of the abdomen did not reveal any abnormal disposition worth registering.

According to the classification of I. Geoffroy Saint-Hilaire,[5] this monster belongs to the class of the Cyclocephaleans; that is to say, to the class of monsters having the nasal apparatus more or less completely atrophied, the apparatus of vision imperfectly formed, sometimes quite rudimentary, directed to the median line and almost always united.

It still belongs to the 'Cyclocephalus' genus, to the cyclocephaleans having a single orbital cavity, two contiguous eyes or a double eye occupying the median line, the nasal apparatus atrophied and no proboscis.

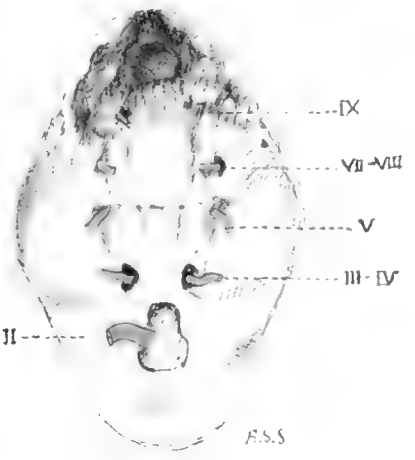
[4] Chauveau and Arloing (loc. cit.) say that the pincers appear from the third to the fifth day, as well as the first mitoyenne. The second mitoyennes would make their appearance about the tenth day after birth.

[5] I. Geoffrey Saint-Hilaire Histoire Générale et particulière des anomalies d'organisation chez l'Homme et les animaux, Paris, 1836.

According to Gurlt's[6] classification, my specimen should be classified as a 'Cyclops arrynchus.'

Besides this cyclops, I have already had an opportunity to study three in the human species.[7] A fetus ♀ Cyclocephalean rhynocephalus, having an ocular globe adherent to the eyelids (1 superior and 2 inferior) without conjunctival culs-de-sac, either superior or inferior. The ocular globe, shapeless, seemed to be formed by two eyes which had fused into one. There were two frontal bones with sutura metopica.

5



6

The second case was a Cyclocephalean cyclocephalus ♂. A superior eyelid and an inferior one, formed, by two soldered palpebrae. Ocular globe atrophied and deformed. Frontal single. Genu varum.

The third case was a skull of a fetus with a median orbit, a single optic foramen, frontal single, very salient frontal and parietal protuberances.

[6] Taruffi-Storia della Teratologia, T. 6, Bologna, 1891.

[7] J. A. Pires de Lima, Sobre tres monstros ciclocefalianos (Anais Scientíficos da Faculdade de Medicina do Pôrto, vol. 4, no. 2).

In an Otocephalean pig ♀ which I studied,[8] the frontal and parietal bones were reduced to a single piece, forming the cranial vault.

An Opodymus cat ♂, which I described,[9] had a concentric orbit with a double eye, apparently rather similar to the single ocular globe of the present observation. However, it has two optic nerves, besides two corneae.

According to Geoffroy Saint-Hilaire,[10] the Cyclocephalean rhinocephali, as in the present observation, mostly have too small an encephalon to fill the cranial cavity; there exists then almost always a larger or smaller quantity of fluid,

In 1860, Gintrac[11] studied a human fetus ♀ born at term, Cyclocephalean rhinocephalus. Its skull was much reduced. The median eye had two corneae and the hind part of the skull a sac full with a lemon-yellow fluid. The brain was atrophied. The olfactory nerve was missing; perhaps also the patheticus, the optic nerves were in close proximity.

Taruffi[12] also mentions the presence of a remarkable quantity of liquid within the skull of the cyclops. The same author records that in these monsters the olfactory nerves are always missing and that there is a single optic nerve with the chiasma absent.

Taruffi, moreover, states that the cyclopia is much more common in the female sex.

Phisalix[13] has studied four monsters cyclocephalean or otocephalean, one in dog, two in sheep, and a human fetus; in the last, attention was immediately drawn by the absence of cerebral hemispheres normally constituted; the skull once opened, there came out a serous, light, opaline liquid, lodged in a sac, at the

bottom of which was the encephalon. Instead of brain, one noted a whitish and flattened mass. In this specimen nerves of the I and IV pair were wanting.

Rabaud,[14] in an extensive memoir, has discussed fifty abnormal chicken embryos, concluding, in accordance with Dareste's opinion, that the cyclocephalia is due to a developmental disturbance of the encephalon.

Watkyn-Thomas[15] has described a human fetus ♀ with incipient cyclopia; it had two eyes drawn nearer and a single nasal orifice, without olfactory nerves. In the Museum of the Anatomical Institute I have stored a similar monster, which I will presently study.

Lately in America several works dealing with cyclopia have been published. I shall mention the following:

Stockard[16] has made some interesting experiments on teratogeny of fishes, artificially obtaining cyclopean monsters by means of solutions of $MgCl_2$ or $Mg(NO_3)_2$ and he believes it may be concluded that such monstrosities in man and other mammals are due to an excess of magnesium salts in the maternal blood or in the amniotic fluid.

Warren Lewis[17] has likewise published experimental observations on teratogeny of fish embryos.

Whitehead[18] has studied a human fetus cyclocephalus.

Chidester[19] has described a cyclopean rat, an atocephalean pig, as well as the brain of a human fetus cyclocephalean. The same author[20] has studied some double monstrosities in fishes, one of them complicated with cyclopia.

Finally, Werber[21] has also occupied himself with experimental teratology and specially with teratophthalmia.

Resumen por el autor, O. F. Kampmeier,
Escuela de Medicina Marquette.

Los cambios en el plan sistémico venoso durante el desarrollo y la relación de los corazones linfáticos de los anuros con estos cambios.

Después de indicar brevemente los trabajos de Goette y Hochstetter sobre el desarrollo del sistema venoso en los anfibios, el autor describe la formación de las venas sistémicas en Bufo. Mediante esquemas demuestra que existe una correspondencia mas estrecha en la disposición primaria y cambios de estas venas en los vertebrados inferiores y superiores, que lo que se ha supuesto. Por ejemplo, el componente subcardinal del sistema venoso existe ya en los estados jóvenes de embriones de anuros. El autor demuestra también como se producen las diferencias, aparentemente irreconciliables, entre la situación de las comunicaciones linfático-venosas del embrión y las de los individuos completamente desarrollados. En el anfibio anuro adulto, por ejemplo, los corazones linfáticos anteriores desembocan en la correspondiente vena vertebral anterior, que a su vez es trigutaria mas anteriormente de la vena yugular interna. En en embrión, por otra parte, el corazón linfático anterior, que se origina a expensas de la vena de la linea lateral que pasa a este nivel, comunica con el seno venoso pronefrótico, que representa la confluencia de las venas pre- y postcardinales alrededor del pronefros. De un modo semejante, los corazones linfáticos posteriores se originan a lo largo de las venas de la linea lateral, pero en el adulto vienen a ponerse en relación con las venas isquiáticas por intermedio de las venas vertebrales posteriores. Los esquemas demuestran además con que facilidad las variaciones tan comunes se producen por la expansión, reducción o persistencia de diferentes segmentos de las venas intersegmentarias originariamente simétricas, cuyas variaciones dan lugar a diferentes relaciones con los troncos venosos principales.

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED
BY THE BIBLIOGRAPHIC SERVICE, MAY 24

THE CHANGES OF THE SYSTEMIC VENOUS PLAN DURING DEVELOPMENT AND THE RELATION OF THE LYMPH HEARTS TO THEM IN ANURA[1]

OTTO F. KAMPMEIER

Department of Anatomy, Marquette School of Medicine, Milwaukee, Wisconsin

NINE FIGURES

Our knowledge of the primary venous plan of anuran embryos and its subsequent transformation is based almost wholly on the observations of Goette and Hochstetter.[2] In his classic work, "Entwicklungsgeschichte der Unke" (1875), Goette gives a clear account of the development of the systemic veins of Bombinator. In some respects, however, the venous system of Bombinator differs from that of the more typical Anura, the most marked difference being the persistence normally of the anterior portions of the postcardinal veins, for which the term 'venae azygae' has generally been employed in the literature. In the retention of the postcardinals alongside of a postcava, Bombinator closely resembles the urodeles, the salamander, for example. Hochstetter ("Beiträge zur vergleichenden Anatomie und Entwicklungs-

[1] This paper represents a section of a larger paper on the origin and development of the lymphatic system in Anura which was originally intended for publication in a monograph, as indicated in The Anatomical Record, vol. 16, August, 1919. Adequate funds were not available to publish that work as such, and it was decided to split it into several parts and have them appear as separate papers in two or three of the anatomical and morphological journals. Though, in a sense, the unity of the work is thereby destroyed, the disadvantage is offset by the advantage of its wider circulation.

[2] For a comprehensive list of the literature on various aspects of the venous system of the Anura, I refer to the following works: "Beiträge zur vergleichenden Anatomie und Entwicklungsgeschichte des Venensystems der Amphibien und Fische," by Hochstetter in Morphol. Jahrbuch, 1888; "Anatomie des Frosches," by Ecker and Wiederscheim, 1896 (Gaupp's revision); 'Vergleichende Anatomie der Wirbeltiere," (7th ed., 1909), by Wiederscheim.

geschichte des Venensystems der Amphibien und Fische," Morphol. Jahrbuch, 1888) has indicated wherein the differentiation of the cardinal system of veins in the frog varies from that in Bombinator.

Since the time of Goette's and Hochstetter's work, no systematic study, so far as the writer is aware, has dealt with the above problem in the light of the more recent work on other vertebrates, nor have the changing relations of the larger venous branches to the main trunks during development been considered. The following diagrams and brief description show that a closer correspondence exists between the lower and the higher vertebrates in the genetic history of their venous systems than has been supposed.

A matter of greater importance in the writer's opinion, is the fact that no account has demonstrated how the seemingly irreconcilable differences between the situations of the lymphatico-venous communications of the embryo and those of fully formed individuals are brought about. This process has interested the writer greatly not only in his investigation of the lymphatic system of Anura, but also in his effort to furnish a systematic presentation of the comparative morphology of the systemic lymphatics in vertebrates.[3] It is a well-established fact that in the adult anuran amphibian the anterior lymph hearts discharge into the corresponding anterior vertebral vein, which further cephalad is a tributary of the internal jugular vein. In the embryo, on the other hand, the anterior lymph heart, arising on the transient vein of the lateral line, communicates with the pronephric venous sinus, which represents the confluence of the pre- and postcardinal veins around the pronephros and is continued to the sinus venosus as the duct of Cuvier. Similarly, the posterior lymph hearts arise along the lateral-line veins, but in the mature form come in relation to the ischiadic veins through the posterior vertebral veins. In comparing the anterior lymphatic taps of an adult anuran with those of a mammal, for example, one would hardly conclude that they are identical, and yet, when their embryonic history is revealed, both can be definitely re-

[3] This work is in process of preparation.

ferred to the cardino-Cuvierian district, where such communications occur with remarkable constancy either temporarily or permanently throughout the entire series of vertebrates, from the lowest to the highest. In the same way, the posterior lymph hearts can be compared with certain members of the lateral series of intersegmental lymph hearts in the tailed amphibians on the one hand and with the iliac and coccygeal lymph hearts of reptiles and birds on the other. Studies like these have impressed the writer, as other investigators have doubtlessly been impressed before, that biological homology becomes an exact science only when it rests squarely on the comparative anatomy of the embryo.

The following account is based almost wholly on a study of the toad, Bufo. The younger embryonic stages belong to the European species, Bufo vulgaris, the later stages, including young individuals shortly after metamorphosis, to the American form, Bufo lentiginosus. Besides these, a few mature frogs, Rana pipiens, were examined. The inserted diagrams have been constructed from a series of graphic reconstructions of the venous system of progressively consecutive stages.

Toad embryos (Bufo vulgaris), 4 to 5 mm. long, possess the primary venous ground plan of vertebrate animals, namely, the simple symmetrical cardinal system, as illustrated in figure 1. There are a number of peculiarities, however, which should be emphasized, since they are directly or indirectly involved in the development of the lymph hearts and associated veins. At the junction of the precardinal (internal jugular) and postcardinal veins, a proportionately large venous sinus (*si. proneph.*) has been formed, a broad plexus of channels which encompass the tubules of the pronephros. Of greater interest are the intersegmental veins (*1-8 v. seg.*),[4] a metameric series of vessels which pass ventrally between the myotomes and epidermis to empty

[4] It should be stated that since there is a possibility of the reduction of intersegmental veins at the extreme anterior end of the series during phylogenesis, just as the spinal ganglion I is an evanescent structure, the designation of the intersegmental veins by specific numerals must be taken with reserve when homologizing Bufo with other Amphibia.

into the cardinal vein trunk, the first three into the pronephric sinus and the remainder into the postcardinal. But not all of them are present at the same time, for in their appearance, as with other events of embryogenesis, the processes of development proceed in an anterioposterior direction. When the foremost intersegmental veins have been established, the more caudal ones may still be lacking, and when these have been laid down and have attained importance, the anterior ones have already begun to disappear or become modified (figs. 1 to 4); only in the lower Amphibia do the intersegmental veins persist as such during the entire life of the animal. Occasionally, too, there are slight irregularities in their arrangement, such as the convergence of two consecutive vessels to join the postcardinal at the same point. But these are insignificant fluctuations, and in the diagrams they have been disregarded.

The original condition of the postcardinal, lying against the medial side of the primary excretory tube of Wolffian duct, is soon altered by the formation of a second channel on its lateral side as the result of longitudinal anastomoses between the intersegmental veins near their points of confluence with the postcardinal (figs. 2 and 3). At the same time, these two parallel channels, which for the time being may be considered as the medial and lateral divisions of the postcardinal (*med.* and *lat. v. card. post.*), become united by numerous transverse anastomoses which pass around, over, and under the Wolffian duct so that this structure becomes enclosed by a cylindrical venous plexus. Hochstetter states that the latter condition only obtains in the salamander, but the writer's material shows without doubt that such takes place normally in the larval Anura as well. At the posterior end of the trunk, the postcardinal vein fuses with its fellow of the opposite side and is prolonged into the tail as the caudal vein (*v. caud.*). Here, too, a paired vessel, the common rudiment of the proximal part of the abdominal and external iliac (*v. iliac.*) veins, branches off and passes laterally around the hind-gut to its under side where it extends forward a short distance.

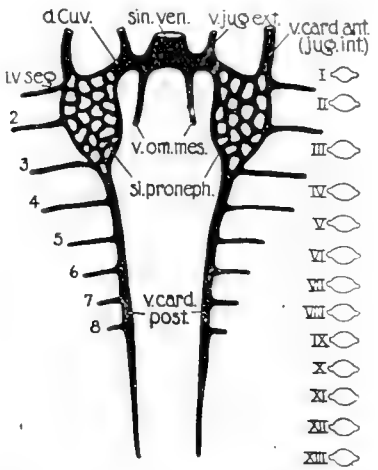

Figure 1

Figs. 1 to 4, diagrams of the systemic veins in 4-, 6-, 7-, and 10-mm. embryos of Bufo vulgaris, respectively; figs. 5 to 7, in 15- and 18-mm. tadpoles of Bufo lentiginosus, and a stage immediately before metamorphosis; fig. 8, in the young toad (B. lentiginosus) immediately after metamorphosis; fig. 9, in a mature frog, Rana pipiens. All figures (except 9), ×33⅓. As all the structures are shown in the diagrams as lying in the same plane, there is, of course, a certain degree of distortion; thus, the intersegmental veins appear to be lateral tributaries of the cardinal veins when in reality they are dorsal ones. The spinal ganglia, I, II, III, etc., were introduced to indicate levels.

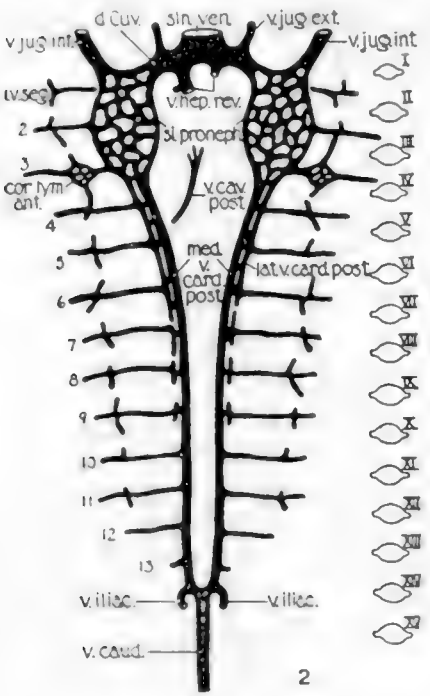
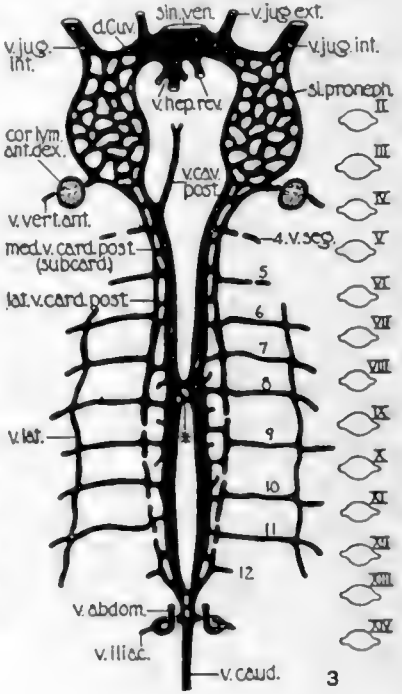
v. subclav., vena subclavia
v. vert. ant., vena vertebralis anterior
v. vert. post., vena vertebralis posterior
*, interanastomosis between the subcardinals

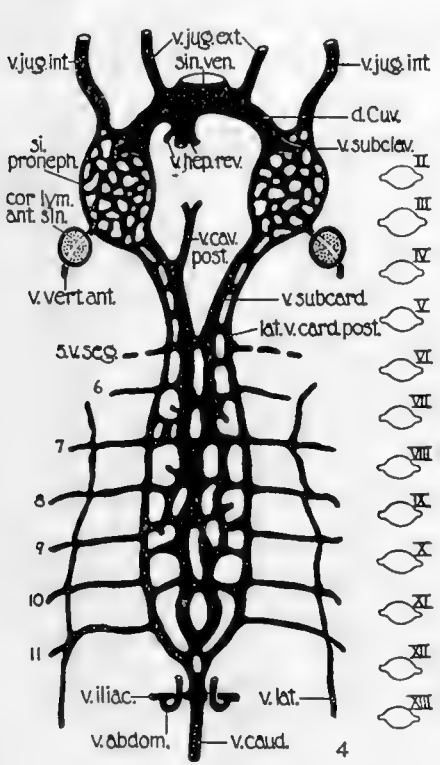
Soon after, in 7-mm. embryos, the two divisions of the postcardinal begin to diverge from one another in the middle of their course (fig. 3) due to the crystallization, as it were, of the anlagen of the mesonephric tubules, which crowd between them. Consequently, the medial postcardinal components, which may now be termed the *subcardinal veins*, since *they are unquestionably the homologues of vessels bearing the same name in higher verte-*

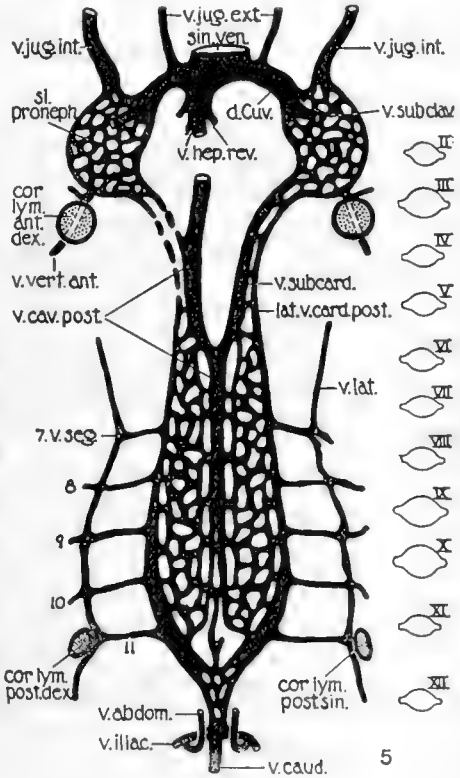




brates, approach each other in the center, and the first hint of their eventual fusion to create the posterior half of the future posteava is offered by a simple interanastomosis (fig. 3,*) at the level of the eighth spinal ganglia. Coincident with the merging of the subcardinals (figs. 4 and 5) occurs the formation of the proximal half of the posteava; this is already potentially present in the right vitelline vein, which, at first equal in size to the left (fig. 1, *v. om. mes*), grows larger (figs. 2 to 5, *v. hep. rev.*), and,

traversing the liver, establishes continuity with an apparently independent segment which is developed between the liver and the right postcardinal (fig. 2). This segment soon becomes confluent with the latter vein at the level of the fourth spinal ganglia (fig. 3), and the postcaval trunk is complete. Obviously,





much of the blood in its return from the caudal regions of the body to the heart is now deflected through the postcava, and in time, as an increasingly greater volume of blood follows this more direct route, the portion of the original postcardinal veins between the postcava and the pronephric sinus of both sides gradually falls into disuse and atrophies, the right disappearing earlier than the left (figs. 5 to 7).

Changes as far-reaching as the above take place caudally. The most distal segment of the subcardinal (medial postcardinal division) does not fuse with its fellow, but undergoes reduction

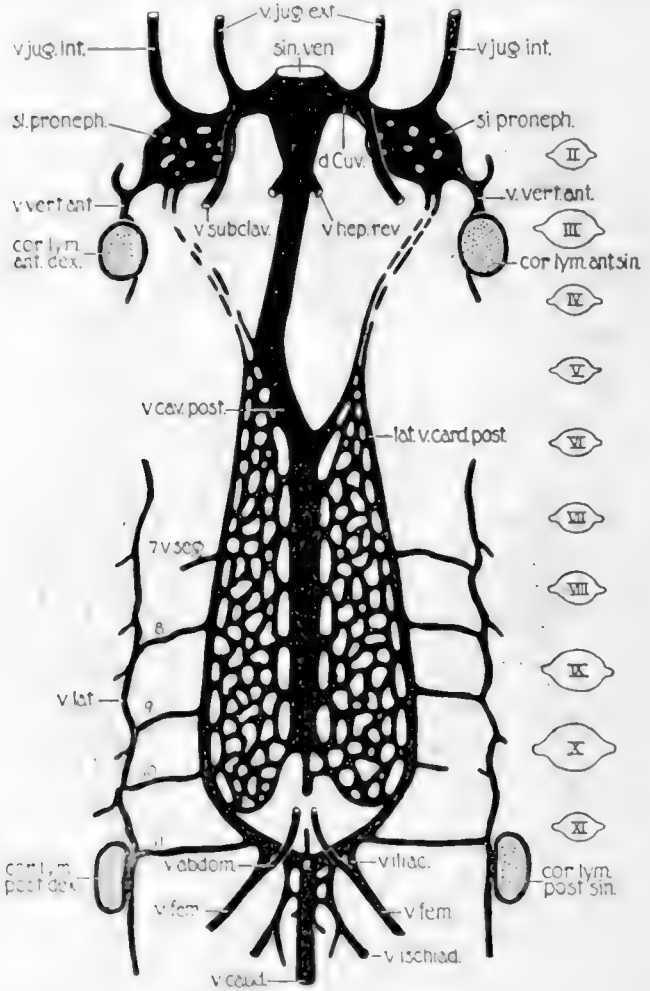


Figure 6

and finally breaks away (figs. 4 to 6), thus severing the connection between caudal vein and postcava. Hence, all of the blood from the hinder regions is compelled to flow through the expand-

ing lateral postcardinal divisions which may now be called the venae renales advehentes (Jacobsen's veins, figs. 7 and 8), thence through the sinusoids of the mesonephroi to enter the postcava

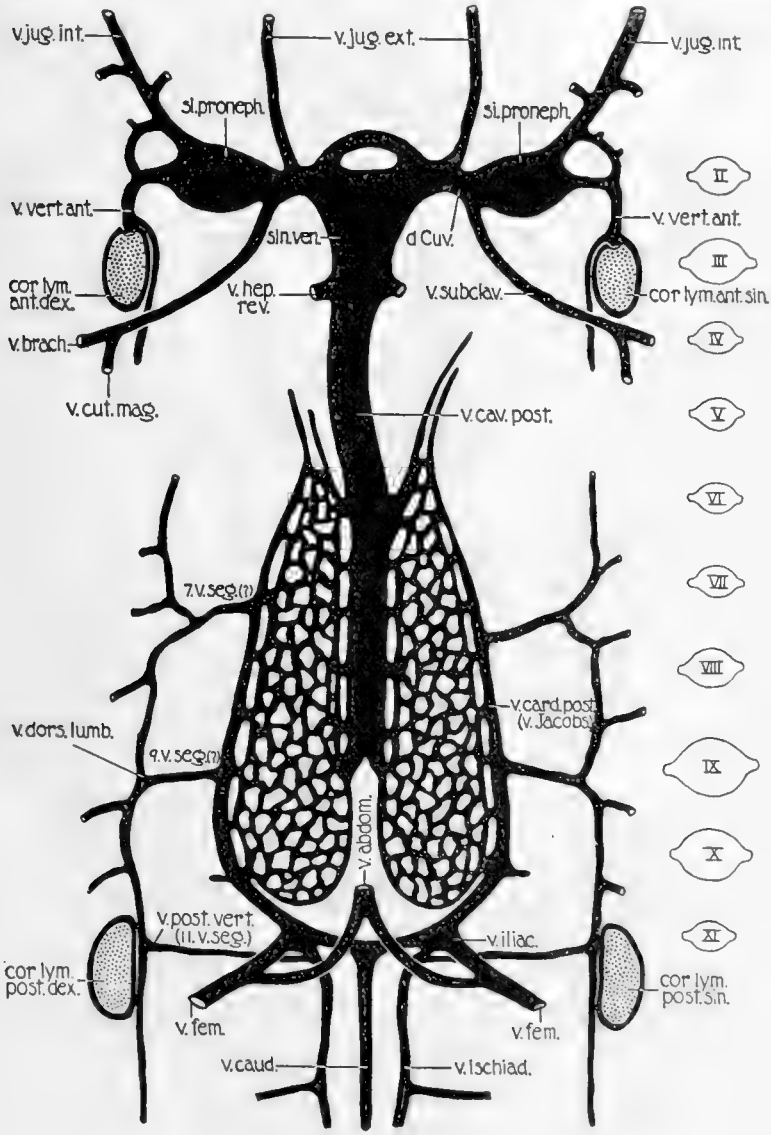

Figure 7

through the revehent branches. In the meantime, the paired abdominal vein has merged anteriorly into a single vessel which joins the hepatic portal vein (not shown in the diagrams) and so produces a second pathway of return for the blood-stream from the posterior region. Gradually, the two unfused and divergent rami of the abdominal vein remain united with the external iliac veins which extend out into the developing limb buds as the rudiments of the femoral veins. Extensions of the postcardinals backward along the caudal vein (fig. 6) represent the anlagen of the ischiadic veins (*v. ischiad.*) which enlarge as the hind extremities develop and the caudal vein degenerates. The transverse iliac veins (*v. iliac trans.*), obliquely connecting the external iliac and ischiadic veins, are a later acquisition (fig. 8).

As the mesonephroi are progressively differentiated and as they assume the function of urea excretion, the pronephroi suffer regression in a corresponding degree (figs. 7 and 8). During the growth of the tadpole a marked shifting of relations occurs, for, as the diagrams indicate, the pronephroi in earlier stages lie slightly back of the niveau of the sinus venosus and are directly placed in the path of the postcardinals, but later, owing to the atrophy of the proximal segment of these channels, they come to lie anteriorly, at the junction of the external and internal jugulars.[5] In fact, the pronephric sinus at the time of metamorphosis forms the terminus of the internal jugular where it appears as a swelling (fig. 8), but the difference in diameter is gradually equalized by further reduction of the sinus. Changes like these are instrumental in bringing about the striking dissimilarities between the venous relations of the lymph hearts in embryonic and in adult stages. Further changes in this region that produce the definitive relations of the anterior lymph hearts to the veins are indicated in the following paragraph.

Associated with the alterations of the large venous trunks, radical modifications take place in the series of intersegmental veins. Another paper will show how the first three of these are intimately concerned in the development of certain lymph-

[5] In using the term 'external jugular vein,' I am following Gruby and Ecker; Goette and many other authors refer to this vein as the 'inferior jugular.'

atic channels, the third contributing largely to the formation of the anterior lymph heart (fig. 2, *cor lym. ant.*). Only the mouth of the anterior vertebral vein (*v. vert. ant.*) of later stages, in

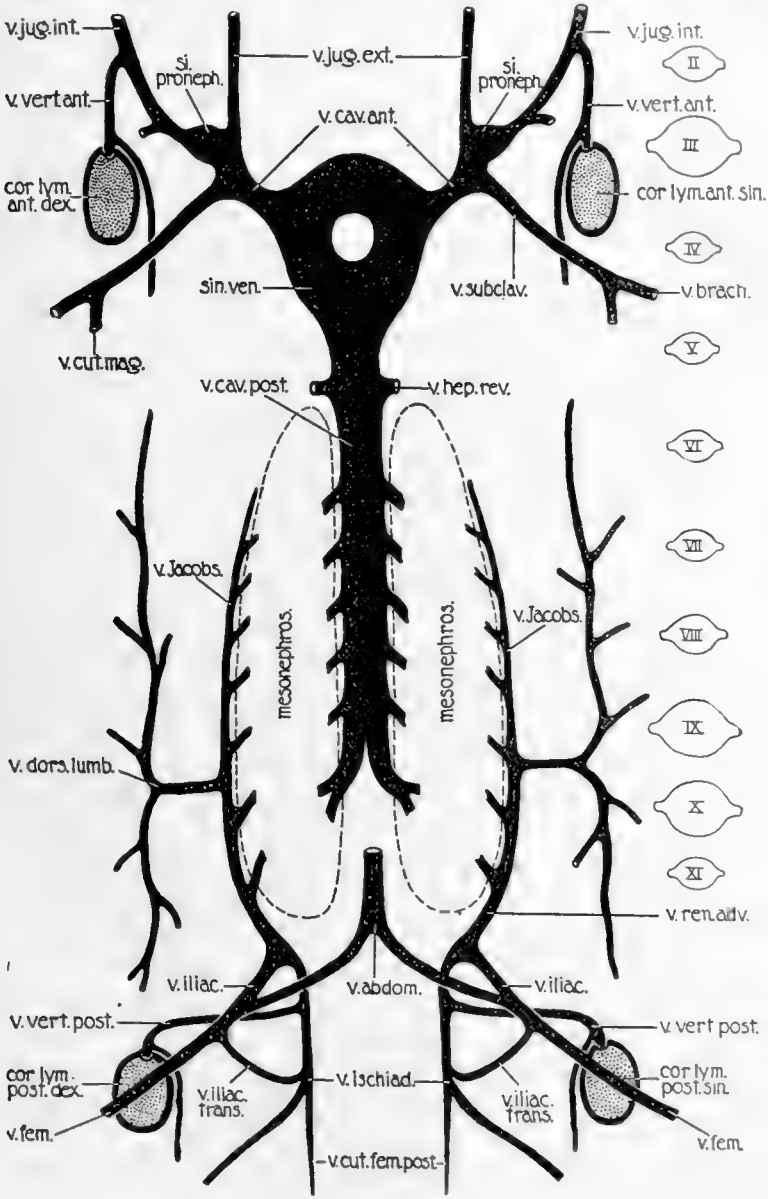

Figure 8

other words, the efferent channel of the anterior lymph heart, can be considered as a direct transformation or derivative of the proximal portion of the third intersegmental vein, the remainder being an outgrowth from the latter just medial to the lymph-heart anlage. During the period of the degeneration of the anterior segments of the postcardinals and the consequent dwindling of the pronephric sinuses, each anterior vertebral vein, besides extending at first in a posterior direction, soon develops a second fork which extends forward and eventually establishes a connection with the internal jugular some distance anterior to the pronephric sinus. Sometime later, the original connection of the anterior vertebral vein with the vestige of the pronephric sinus, now the terminal portion of the internal jugular, breaks away, and the secondary junction farther cephalad becomes the permanent outlet of the lymph stream from the anterior lymph hearts. These changes are clearly expresedin the diagrams 5 to 8, inclusive.

During development all of the intersegmental veins back of the anterior lymph hearts become interjoined by a longitudinal anastomosis (figs. 2 and 3) which may be termed the lateral vein (*v. lat.*) because it courses in the lateral-line region and is without doubt homologous with a similar vein in the tailed amphibians. Subsequently, the termini of all intersegmentals except the 9th and 11th (fig. 7) in toad embryos become very much reduced or vanish, although variations happen, such as the persistence of the vessels in intervals other than those. The anterior one of the retained intersegmentals becomes the transverse piece or mouth of the dorsolumbar vein (figs. 7 and 8, *v. dors. lumb.*), while the greater extent of the lateral vein becomes its longitudinal portion (rami iliolumbalis and iliacus). While these changes are taking place, the posterior lymph heart (*cor. lym. post.*) on each side[6] develops from a lymphatic plexus along

[6] Bufo possesses only one posterior lymph heart on each side. Among the frogs there are multiple posterior lymph hearts, from two to four in number on each side in the adults; thus in the American common species, Rana pipiens, there are normally two pairs of these (diagram 9) with the occasional vestige of a third, present in the tadpole. The development of these hearts and their relation to the veins will be considered in one of the subsequent papers.

the lateral vein at the level of its 11th intersegmental branch (fig. 5). The proximal portion or junction of the latter branch with the postcardinal (vena renalis advehens) becomes the mouth or terminal segment of the posterior vertebral vein (*v. vert. post.*) and the caudal part of the lateral vein becomes its distal extension (figs. 7 and 8). A break occurring in the lateral vein between the two parts of it, referred to the longitudinal portion of the dorsolumbar and the posterior vertebral veins, respectively, establishes the independence of these two veins.

In the meantime the posterior lymph hearts have formed a connection with the corresponding posterior vertebral veins, so that these channels now become the outlet of the lymphatic drainage of the posterior region of the body. The shifting of the mouth of the posterior vertebral vein back along the ischiadic vein up to the point where the transverse iliac vein is forming is clearly indicated in figures 7 and 8. These diagrams show how easily the variations that are so common arise by the expansion, reduction, or persistence of different segments of the originally symmetrical intersegmental veins, resulting in different relations with the main venous trunks.

The degree of displacement, during development, of the various components of the venous conduit system, brought about by the more rapid elongation of some and the suppression of others, may be readily determined by comparing the successive stages with reference to the relatively fixed positions of the spinal ganglia, as indicated in the diagrams.

Resumen por el autor, H. E. Jordan,
Universidad de Virginia.

Estudios sobre la estructura del músculo estriado.

VII. El desarrollo del sarcostílo del músculo alar de la avíspa, con consideraciones sobre la base fisicoquímica de la contracción.

La estructura del sarcómero del relativamente grosero sarcostilo del músculo alar de la avíspa susministra la base de un intento de explicación fisicoquímica consistente sobre la contracción muscular. Las metafibrillas extremadamente pequeñas que constituyen este sarcostilo, homólogo de la miofibrilla del músculo estriado de los vertebrados, exhiben durante la contracción exactamente los mismos cambios estructurales que la fibra muscular estriada voluntaria en conjunto. El cambio esencial durante la contracción se refiere a la división igual de la substancia fuertemente tingible del disco Q al nivel del mesofragma y el movimiento de las mitades resultantes en direcciones opuestas, aplicándose contra los telofragmas terminales del sarcómero, donde se forman las bandas de contracción. La causa de la contracción muscular está localizada en este movimiento de cristaloides entre las partículas coloidales (submicras) de los segmenos claros terminales. El acortamiento y aumento de espesor de los sarcómeros durante la contracción se interpreta como el resultado de un cambio en la forma de las partículas coloidales intrafibrilares que pasan de la forma elipsoidal a la esférica, a causa de un aumento en su tensión superficial resultante de la disminución de sus cargas eléctricas superficiales, la cual sigue al paso de electrolitos entre ellas durante el movimiento de la substancia fuertemente tingible desde el mesofragma a los telofragmas.

STUDIES ON STRIPED MUSCLE STRUCTURE

VII. THE DEVELOPMENT OF THE SARCOSTYLE OF THE WING MUSCLE OF THE WASP, WITH A CONSIDERATION OF THE PHYSICO-CHEMICAL BASIS OF CONTRACTION

H. E. JORDAN

Department of Histology and Embryology, University of Virginia

THIRTEEN FIGURES (TWO PLATES)

INTRODUCTION

In the last number of this series of studies[9] it was shown that the constituent sarcostyles of the wing muscle of the wasp exhibit the same changes during contraction, with respect to the cross-striations, as do the complete fibers of striped muscle generally, namely, a reversal of striations as regards a deeply staining substance of the dim disc. It was assumed that the relatively coarse, cylindric sarcostyle of the wasp's wing muscle is the homologue of the more delicate myofibrils of vertebrate striped muscle. If this assumption accords with the facts, then Schaefer's[15] explanation of the appearance of a reversal of striations during contraction, as an optical illusion due to the accumulation of intersarcostylic fluid at the telophragma levels of relative constriction, must be erroneous. Moreover, the idea that this sarcostyle during functional contraction swells at the levels of the dim discs, thus producing a relative constriction at the level of the telophragma, is itself erroneous. As was shown in the previous number,[9] the beaded condition of the sarcostyle is the result of an artificial contraction following the osmotic action of a hypotonic medium. The functionally contracted sarcostyle, while it shortens and thickens, maintains meanwhile, nevertheless, a straight, unbeaded contour. None the less it seems desirable to establish definitely the actual morphologic status of the wasp's wing-muscle sarcostyle by a study of its development.

This is the primary purpose of this investigation, namely, to trace the developmental history of the wasp's wing-muscle sarcostyle with a view to determining its value in terms of the elementary myofibril of vertebrate striped muscle. The evidence which will be given below seems conclusive that the sarcostyle of the wasp's wing muscle and the myofibril of vertebrate striped muscle are actually strictly homologous elements. This being so, it follows that in our efforts to discover the ultimate physicochemical basis of contraction we may more profitably, and quite legitimately and confidently, confine ourselves to the relatively much coarser sarcostyles of certain insects' wing muscle (e.g., Diptera, Hymenoptera, and Coleoptera). The second purpose of this investigation is finally to attempt a physicochemical interpretation of the structural changes suffered by the sarcostyle during contraction, and to formulate a consistent hypothesis in explanation of the cause of muscle contraction. The entire series of these studies on muscle structure had for one of its chief objects the accumulation of sufficiently numerous and precise data for the establishment of a correct physicochemical interpretation of muscular contraction.

MATERIAL AND METHODS

The material available for this study consists of two fairly complete series of specimens ranging from the newly hatched larva to the older pupae, one series fixed in 95 per cent alcohol, the other in a 10 per cent solution of neutral formol. For this material I am indebted to Mr. Massie Page. For the purposes of the present problem we may confine ourselves to four salient developmental stages: 1) the oldest larval stage (or youngest pupal stage), namely, one in which the thorax is outlined and wing pads are discernible, but no external leg rudiments; 2) an intermediate white pupa; 3) a later gray, or slightly pigmented, pupa, and, 4) the black, almost mature, pupa. The thorax was embedded in paraffin. Sections were cut at 4μ, and stained with iron-hematoxylin, followed in some cases by eosin counterstain.

DESCRIPTION

In the youngest, legless pupal stages very delicate wings are already present. Serial sections through the thorax show the imaginal discs still in continuity with the ectoderm ventrocaudally. Here, then, occur the initial myoblasts (fig. 1, *a* and *b*). Older stages in the muscle histogenesis occur anterodorsally (fig. 3 and 4). Between these terminal levels occur intermediate developmental stages (fig. 2, *c*).

The initial myoblasts are long, fusiform elements with a vesicular, centrally located nucleus. The nucleus originally contains a single, dense, chromatic nucleolus. The latter subsequently divides, the nucleus now containing a pair of nucleoli. This condition foreshadows the ensuing direct nuclear division. The myoblasts fuse terminally, their tapering ends overlapping (fig. 1, *b*), to form the definitive muscle fibers. Meanwhile the nuclei multiply greatly by amitotic division. No mitotic figures were seen in the myoblasts or later muscle fibers at any stage. The muscle fiber accordingly arises by fusion of originally discrete cells, not solely and primarily by growth of the myoblasts. The nuclei multiply by direct division chiefly in planes perpendicular to the long axis of the myoblasts, thus forming axial columns of nuclei (fig. 1, *b*); but to some extent also by division in the longitudinal plane, thus originating more peripheral nuclei. Appearances like those illustrated in figure 2, *c*, represent in part the latter sort of division, but in part also no doubt levels of sections where the tapering ends of fusing myoblasts overlapped.

Already in the earliest myoblasts, like those of figure 1, *a*, an occasional peripheral myofibril is faintly discernible. The nature of this material does not permit of any definite statement regarding the origin of the myofibrils. I am unable to determine whether the original fibrils arise as such or by the alinement and subsequent coalescence of precursory myochondria. Nor can I be quite certain whether later fibrils arise by longitudinal division of preexisting myofibrils, or independently. I incline to think that the later myofibrils arise chiefly independently; at

any rate, there is no clear evidence of a longitudinal splitting. The fibrils soon extend uninterruptedly through several original cell limits, and they remain for a relatively long time homogeneous. In figure 2 (*a* and *b*) are illustrated transverse sections of myoblasts corresponding with *a* and *b* of figure 1. Illustration *c* of figure 2 represents an older myoblast. Connective-tissue cells occur among the myoblasts. At least some of these divide by mitosis. Many of these cells become fat-cells. The cell *c.t.* of figure 2 is at an early stage of differentiation into a fat-cell.

The earlier muscle fibers, formed by the fusion of myoblasts, grow rapidly in diameter (fig. 3). Both nuclei and myofibrils meanwhile undergo enormous numerical increase. In a transverse section (fig. 3) the nuclei, now granular and more chromatic, appear to be scattered at random. Longitudinal sections of fibers at this stage (fig. 4), however, show that the nuclei are arranged in long columns, in single or double file. The connective tissue cells have also meanwhile increased greatly in number. The interfiber spaces have a diameter approximately equal to that of the muscle fibers. These spaces are closely packed with stout, fusiform, and irregular connective-tissue cells. The latter subsequently differentiate largely into huge fat-cells. The myofibrils are still homogeneous and quite delicate. In transverse section they have the appearance of fine granules (fig. 3).

Passing now from the stage of the oldest larva to that of the white pupa, with well-developed wings and legs, the wing-muscle fibers are seen to have enlarged enormously (fig. 5). The nuclei are numerous, but of smaller size in transverse section than in the preceding stage. Longitudinal sections of such fibers (fig. 6) reveal the fact that many of the nuclei are now greatly elongated elements. These continue to divide amitotically. The fiber is enveloped by a delicate sarcolemma. In certain cross-sections the peripheral myofibrils appear to be arranged in radial lines (fig. 5). This is the sole evidence that myofibrils may in part arise by longitudinal splitting of preexisting fibrils. The myofibrils are now relatively coarse (figs. 5 and 6), but still clearly unstriped, and between the fibrils appears a very finely granular sarcoplasm (fig. 6).

Thus far there is no indication of even a telophragma. In a slightly older pupal stage (gray pupa), however, this membrane has made its appearance (fig. 10). The myofibrils, or sarcostyles, are now relatively very coarse, as may be seen by comparing figure 7 with figure 5 of the previous stage, and with figure 8 from the adult muscle. The stages of muscle development in the gray pupa are of the utmost significance in this connection. We meet here with the initial steps in the origin of the cross-striations due to the presence of dim discs. Certain large masses of fibers are composed of sarcostyles in which only the telophragmata have appeared (fig. 9, *a*). In other masses the sarcostyles contain also delicate, but deeply staining, Q-discs (fig. 9, *b*). In such sarcostyles the telophragma has changed to an only relatively faintly staining membrane. Still other large masses of fibers consist of sarcostyles with relatively wide Q-discs (fig. 9, *c*). In certain other groups of fibers the Q-discs appear double (fig. 9, *d*), and occasional sarcostyles of such groups reveal very clearly constituent finer elements, the metafibrils (fig. 9, *e*). The clear indication of metafibrils, as in *e* of figure 9, may probably represent an artificial condition; but that the sarcostyles actually are composed of still finer fibrils seems demonstrated by the conditions which obtain where the muscle is attached to the hypoderm (fig. 10). Here the sarcostyles appear to break up into very fine 'tendinous' fibrils. The transition from muscle to tendon appears to be through direct continuity of muscular metafibrils and tendon fibrils The latter stain deeply in very dilute solutions of eosin, in contrast with the muscle which remains unstained. The metafibrillar composition of the sarcostyles is a point of cardinal significance with respect to the physicochemical explanation of contraction, and will be fully discussed below.

The order of development of the cross-striations here disclosed is also a fact of much importance. The Q-disc appears only after the telophragma becomes discernible. The Q-discs are at first only very delicate, and only gradually attain their typical width between successive telophragmata. Coincident with the appearance of deeply staining Q-discs, the telophragmata suffer

a diminution of staining intensity. The meaning of the double condition of the Q-discs, as in figure 9, *d*, is uncertain. It may have the same significance as in the mature sarcostyles, namely, indicative of an early phase of contraction.

The foregoing observations are specially significant by reason of the light they throw on the question of the function of the telophragmata. The data strongly suggest that the telophragmata furnish the pathways along which are transported the materials which contribute to the formation of the dim discs, as well as the materials which supply the nutritive demands of the sarcostyles. The genetic order of events here revealed explains the horizontal alinement of striations in cross-striped muscle. This matter also will be reverted to and more fully discussed below.

Thus far no evidence appears, either in the formalin or alcohol-fixed preparations of sarcosomes. The latter appear first in formalin-fixed muscle of the almost mature black pupa (figs. 11 and 12). A largely lipoid nature of these sarcosomes is suggested by the fact that they entirely disappear in muscle of this stage fixed in 95 per cent alcohol. The sarcostyles have attained almost their definitive diameter (compare figs. 12 and 8 and figs. 11 and 13). In longitudinal sections (fig. 11) the sarcosomes appear spheroidal, but transverse section at this stage reveal the fact that they are already laterally somewhat compressed, and so possess short, blunt, lateral wings (fig. 12). Generally only two sarcosomes occur to an intertelophragma space, indicating that the telophragmata offer an effective barrier against their passage through these levels, and suggesting that the materials for their elaboration were also transported through the telophragmata, a sarcosome each being contributed by one telophragma. Comparison of figure 12 with figure 8, the latter from an adult muscle, shows that the sarcosomes undergo considerable subsequent growth, a circumstance involving still greater compression between adjacent sarcostyles, with the formation of longer, thinner wing processes. The relatively late origin of the sarcosomes, that is, just prior to functional activity of the wings, suggests a close relation between

sarcosomes and the metabolic requirements of the relatively very rapidly contracting wing muscle.

In figure 13 are illustrated three successive stages in the contraction of the sarcostyle of the wing muscle fiber of an adult wasp. The sarcostyle *a* is in a condition of repose. The sarcostyle *b* is at an early phase of contraction. The Q-disc has become bisected by the appearance of an H-disc. The deeply staining substance of Q is accumulating at the levels nearest the telophragmata. The sarcostyle *c* is at a still later phase, when the deeply staining substance of the sarcoplasm has aggregated about the telophragma, so that now this membrane bisects a dark disc, instead of bisecting a light disc as previously. A true reversal of striations, as regards this deeply staining constituent of the sarcoplasm, has been effected. Sarcostyle *d* is in almost complete contraction. The sarcostyle has become thicker, and the sarcomeres relatively shortened. The deeply staining substance about *Z* in sarcostyle *c* has here condensed so as to form a contraction band of the contracted fiber. The double nature of this band is clearly shown in sarcostyle *d*. The telophragmata are, however, no longer discernible. The optical disappearance of the membrane *Z* in sarcostyle *d* is interpreted as resulting from the thickening of the sarcostyle, effecting thus a drawing out radially and a consequent thinning of this membrane to a point where it is no longer within the range of microscopic vision.

The above seriation of stages in contraction of the adult sarcostyle gives the key for the interpretation of figures 11 and 9, *d*, of immature sarcostyles. Sarcostyle *d* of figure 9 would thus appear to be in an early stage of contraction, the sarcostyle of figure 11 at a later stage corresponding with that of *c* of figure 13. Apparently the immature sarcostyles are capable of some degree of functional contraction even before the wings are moved in flight.

DISCUSSION

The foregoing description shows that the wing-muscle fiber of the wasp is essentially homologous with voluntary striped-muscle fibers generally. The fiber is a multinucleated structure resulting from the fusion of originally discrete myoblasts, and subsequent growth, accompanied by an increase in the number of myofibrils and by the amitotic multiplication of the nuclei. The fibrils first appear as homogeneous elements, which only later become cross-striped. The wing muscle of the wasp, as that of Hymenoptera, Diptera, and Coleoptera generally, differs, however, from the usual type of voluntary striped muscle, in the definitive stages of its differentiation, in that its fibrils grow to relatively enormous radial dimensions. But the developmental history of this relatively very coarse sarcostyle demonstrates its strict homology with the more delicate myofibrils of vertebrate skeletal muscle.

The question then arises concerning the functional significance of the relatively coarse sarcostyle of certain insects' wing muscle. Clearly the coarse, cylindric condition of the sarcostyle bears no direct causal relation to flight as such even among insects, since in the Orthoptera and certain Odanata the wing muscle fibers of the thorax are characterized by lamellar 'sarcostyles' with constituent very delicate myofibrils. When we seek for a possible explanation of the difference in girth of sarcostyles in the several groups of insects, we note the fact that what distinguishes the flight of Diptera, Hymenoptera, and Coleoptera from that of the Orthoptera, for example, is not so much the rapidity of flight as the ability on the part of the former groups to sustain rapid flight for relatively long periods of time. The suggestion then presents itself that a relatively coarse type of sarcostyle, characteristic of wing muscle of which is demanded long-continued function, may somehow better subserve the conditions of this demand than a structure characterized by relatively delicate cylindric or by lamellar sarcostyles. Such hypothesis is supported also by the fact that the sarcostyles of the analogous pectoral muscles of the humming bird and the bat are

relatively coarse cylindric structures. However, all speculations along these lines lose plausibility in view of the definite fact that also the coarse, apparently unitary, sarcostyles of wasp wing muscle resolve themselves finally into extremely minute constituent fibrils (metafibrils). This is true also of the lamellar type of wing muscle sarcostyle (e.g., mantis[8]). It might then perhaps be argued that the coarse, so-called sarcostyle of the wasp's wing muscle is not actually the homologue of the myofibrils of, for example, human leg muscle, but in fact represents a fascicle of such fibril homologues. The apparent force of such argument, however, is neutralized by the fact that also the myofibrils of mammalian skeletal muscle may be seen to consist of collections of still finer fibrils. The sarcostyle of the wasp's wing muscle differs, moreover, from the lamellar, so-called sarcostyle of Orthoptera, in that the latter includes relatively fewer constituent fibrils and relatively much larger quantities of intrasarcostylic non-fibrillar sarcoplasm. Successively more detailed analysis of muscular fibrils reveals successively finer constituent meta-fibrils up to the limits of visiblity. As above described, however, and already explained, the early stages in the development of the wasp's wing-muscle sarcostyle show that it is strictly homologous with the myofibril of vertebrate striped muscle. Clearly, also, rapidity of function, or long-sustained function, is not directly related to complexity of cross-striation; for the wasp's wing muscle, and vertebrate cardiac muscle, is characterized by a relative simplicity of striation. Complexity of striation, resulting from the presence of an additional N-disc, as in insect leg muscle generally, would thus appear to be related to force of function rather than to rapidity or long continuance of function.

Insect wing muscle generally, however, differs from voluntary striped muscle of vertebrates in the occurrence of numerous, relatively large sarcoplasmic granules or sarcosomes in the former. But comparable elements occur also in the analogous pectoral muscles of bats and birds (Thulin[16]), and in mammalian heart muscle (Bullard[1]). The common factor in the conditions underlying the peculiar function of these three types of muscle is the

ability of long-sustained function. The evidence suggests that large and abundant sarcosomes subserve the peculiar metabolic needs of muscles which act continuously for long periods of time. The absence generally of at least large and abundant sarcosomes in insect leg muscle, and in vertebrate skeletal muscle generally, suggests that forceful function only at intervals does not necessitate exactly the same type, or at least the same degree, of support of its metabolic requirements.

The sarcosomes develop relatively late. They appear first in the almost mature (black) pupa (fig. 11). They are at first spherical in shape; subsequently they become modified into winged elements, the result of mutual pressure between the adjacent growing sarcostyles and the enlarging sarcosomes. As was suggested in a previous article,[9] the winged type of sarcosome probably largely persists throughout the life of the individual. Microchemical evidence was also given indicating that, besides a predominant lipoid constituent, the sarcosomes, at least in the later phases of elaboration, include an additional substance, possibly a carbohydrate. The very definite arrangement of the first formed, spherical sarcosomes, two to each sarcomeric interval, suggests that the material for their elaboration enters the intersarcostylic spaces via the telophragmata.

A detail in muscle histogenesis about which there has been much confusion and unprofitable speculation concerns the fact of the regular horizontal alinement of identically differentiated levels of the cross-striped myofibrils of a striped muscle fiber. The question arises as to how these alternating discs of adjacent fibrils are first brought into horizontal alinement. If the cross-striped myofibrils arise originally independently of telophragmata, as the illustrations of Godlewski[2,3] and of Luna[11] for example, purport to indicate, then it is almost inconceivable how they may subsequently be brought into horizontal alinement. Whatever idea different investigators may hold regarding the origin of the initial myofibrils in various instances, whether as fibrils, mitochondria, or as prefibrillar myochondria which subsequently coalesce to form fibrils, all agree that the first genuine myofibrils are originally apparently homogeneous and only sub-

sequently become cross-striped.[1] The illustrations of Godlewski, while showing cross-striped myofibrils unconnected by telophragmata in young myoblasts of mammals, give no indication of how the secondary myofibrils originate. Possibly Godlewski failed, or was unable by reason of their extreme tenuity, to see the telophragmata actually spanning the interfibrillar spaces among the original myofibrils. Be this as it may, we possess two definite observations which explain how this transverse alinement of identically differentiated levels of the myofibrils of a muscle fiber is produced.

The clearest evidence concerning this point accrues from the present investigation. It seems perfectly plain in this material that telophragmata precede the appearance of Q-discs (figs. 9 and 10). It was shown in previous papers[5,6] that the telophragmata are intimately connected with the sarcostyles and with the peripheral sarcolemma. In this way each sarcostyle is brought into relation with the interfiber tissue spaces and thus with the nutritive tissue fluid. Assuming that the telophragmata are pathways for the entrance and exit of materials between the

[1] M. R. Lewis, however, claims that in the myocardium of the chick embryo it can be demonstrated by a certain fixing and staining technic that the 'fibrils' are completely cross-striated from their first appearance (Johns Hopkins Hospital Bulletin, vol. 30, p. 1). Moreover, she interprets the 'fibrils' as fixation products, a view long since urged for striped muscle geneally by Van Gehuchten (La Cellule, T. 4, p. 247, 1888), but never widely accepted. The cross-striations she regards as genuine fundamental structural features of the myoblast as a whole. If the conclusion here reached with regard to the artificial nature of the fibrils of the primitive myocardium of the chick were applied to the wing muscles of the wasp, we would be obliged to interpret the sarcostyle (homologue of the vertebrate myofibril, as above demonstrated) of the latter muscle as a developed and differentiated fixation product; since, no one I suppose, would seriously attempt to explain this definitive sarcostyle of adult wing muscle of wasp as also an artifact. It may be suggested that the reason why the primitive myofibrils described by certain investigators in cardiac muscle are not discernible microscopically in living myoblasts is not because they are not actually present, but because they are relatively fluid and because in consequence the refractive index of their sarcoplasm is so close to that of the interfibrillar sarcoplasm that the contrast between the two is insufficient to permit of clear differentiation under the microscope. The coagulative effect of fixation may bring about a greater relative difference between the refractive indices of the two sarcoplasmic colloids, and so render visible the denser fundamental sarcoplasmic fibrils.

sarcostyles and the interfiber tissue spaces (and this would appear to be their chief function), it becomes clear why the secondary modification of the originally homogeneous sarcostyles, namely, the formation of the Q-discs, follows the development of the telophragmata. Such genetic course explains at once the reason for the maintenance of a strict transverse alinement. The investigations of Macallum[12] and of Menten[13] have shown that the dim discs contain potassium salts, chlorides, and phosphates. The presence of these substances in these regions may be the reason for their deeper staining capacity. These substances, considered physicochemically, are soluble crystalloids, at least in part electrolytes, and their segregation in the middle of the colloidal sarcomeres against the mesophragma, after entrance is thus explained.

The difference in staining reaction of the telophragmata at the several successive early stages in the development, from the viewpoint of the relative amount of Q-substance, supports the idea here advocated, namely, that the materials for the production and growth of the Q-discs enter via the telophragmata. In figure 9, *a*, the telophragmata are relatively coarse and stain deeply. In *b*, where a thin Q-disc has appeared, the telophragmata are now delicate and relatively pale. The sarcostyle *a* may be interpreted as at the stage where the telophragmata are saturated with the deeply staining material, which in *b* has become segregated in the delicate Q-disc. To the latter is later added more of similar material to produce the relatively thick Q-disc of sarcostyle *c*. In view of the fact that the sarcostyles are closely connected with the telophragmata, the subsequently stratified sarcostyles (differentiating in the manner indicated through segregation of crystalloids entering the colloidal sarcomeres through the telophragmata) must of necessity hold their alternating strata in horizontal alinement.

The other pertinent observation in this connection concerns the mode of the development of the myofibrils in the body muscle of the newly hatched rainbow trout.[5] The same histogenetic series of events in trout has been described also by Heidenhain.[4] Here the myoblasts originally contain a single, coarse, homo-

geneous, deeply staining, cylindric myofibril lying close to the nuclear wall within the cytoplasm. The origin of this initial sarcostyle could not be determined. This primordial sarcostyle produces four secondary sarcostyles by two practically simultaneous longitudinal divisions. These secondary sarcostyles assume a stout lamellar form, and subsequent sarcostyles arise only by successive radial and central longitudinal fissions. Thus while the sarcostyles, both peripheral lamellar and central cylindric, become cross-striped during the early stages of histogenesis, all subsequent myofibrils must maintain a similar alinement of their different alternating strata by reason of their origin by longitudinal division of already striped fibrils and their continued interconnection through the original telophragmata. Telophragmata are discernible following the first division of the initial sarcostyle. The available definite evidence therefore indicates that the cross-striations, as regards the Q-discs, only follows the appearance of telophragmata connecting with the peripheral sarcolemma, and so with the interfiber tissue spaces; and that the stratification results from the intake via the telophragmata of soluble crystalloids which become segregated in the Q-disc.

The foregoing descriptions and discussions, together with the data comprised in the previous papers of this series, lead naturally to an attempt to formulate a correct interpretation of the structural changes which the sarcostyle undergoes during contraction, in terms of physicochemical factors, and to an effort to explain muscle contraction in terms of these changes. The specific central problem narrows itself down to a question of the intimate structure and physical chemistry of the contracting single sarcomere of the relatively coarse sarcostyle of the wasp's wing muscle.

The sarcomere is bounded at both ends by a true membrane, the telophragma. Its middle is occupied by a disc of variable width, the so-called Q- or dim disc. This disc is composed of a substance which appears darker in unstained preparations, and which takes a deeper stain in fixed preparations treated with basic dyes. It contrasts in these respects with the lighter por-

tions, halves of so-called J- or clear discs, intervening between it and the terminal telophragmata. The sarcomere is bounded peripherally by a layer which has the properties of a semipermeable membrane, as demonstrated by its response to hypo- and hyper tonic salt solutions. This layer, the sarcostylic membrane, is intimately connected with the telophragmata. Bisecting the Q-disc there occurs a delicate dividing structure, presumably a membrane, as demonstrated by the equal division of this disc in contraction along the midline, the mesophragma. This membrane, however, is not discernible as such in this sarcomere under the highest powers of the microscope. Minute analysis reveals the fact that the apparently homogeneous sarcomere consists in fact of ultimate metafibrils. The latter are intimately attached to the telophragmata. Macallum[12] and Menten[13] have shown that the Q-disc contains segregated chlorides, phosphates, and potassium salts. The presence of these substances in this area presumably accounts for the 'dim' appearance and the deeper staining capacity, possibly also for the relatively greater anisotropy, of this disc in contrast with the terminal J-segments. These salts represent soluble crystalloids, therefore, at least in part, electrolytes, and give to the Q-disc a composition physicochemically different from the predominantly colloidal terminal clear portions. The sarcomere, therefore, consists of a cylinder of minute fibrils enveloped by a peripheral membrane, each colloidal fibril containing medially a mass of segregated crystalloids. Through the terminal telophragmata of the sarcomere, each fibril (metafibril) is placed in capillary relation with the intersarcostylic fluid spaces. Presumably there exist between the metafibrils capillary interfibrillar canaliculi. When the muscle contracts, the predominantly crystalloidal medial disc (Q-disc) of each metafibril of the sarcostyle divides along the midline (mesophragma level) and the resulting halves move in opposite directions to fuse with similar halves, from successive sarcomeres, along the terminal telophragmata, thus forming contraction bands. The contraction bands accordingly represent discs of predominantly crystalloidal composition, and a reversal of strata (striations) as regards the deeply staining crystalloidal substance of the relaxed sarcostyle has occurred during contraction.

The problem of muscle contraction, therefore, resolves itself, in the final analysis, into a physicochemical explanation of the shortening and thickening of the sarcomere in relation to the movement of a medial mass of crystalloids (electrolytes) through the terminal colloidal segments against the telophragma boundaries. It is here assumed that the movement of crystalloids among colloids is the cause, not simply the accompaniment, or the result, of contraction.

The solution of the above-stated problem involves also an explanation of why, during the original determination of the stratified condition of the sarcostyle, the crystalloids, presumably entering terminally via the telophragmata, take a definite median position. The attempt at such explanation must first be disposed of. In regard to this aspect of the complete problem, we are actually dealing with a colloidal compartment, a hydrogel of myosin, bounded on the side where the crystalloidal substance presumably enters by a relatively coarse telophragma, at the opposite end where it is deposited, by a relatively delicate mesophragma. When crystalloids mingle with a colloid, the molecules of the latter suffer a change of surface electrical charges, and it may be assumed that the crystalloidal particles or ions are repelled (or perhaps simply passively carried by fluids, due to the fusion of collodial particles behind thus propelling fluids forward) to the limit where they are held by the mesophragma and the adjacent mass of electrolytes.[2] The electrical condition of the now polarized sarcomere may now be considered to be in stable equilibrium in the resting fiber. Whatever the original form or state of aggregation of the colloidal particles, the passage of the crystalloidal particles, and their

[2]The manner of origin of the initial stratification may perhaps be comparable to that of the so-called Liesegang phenomenon of colloidal chemistry, which phenomenon occurs when a gel containing a substance in solution is treated with a second solution capable of reacting with the solution in the gel; e.g., when to a test-tube partly filled with 1 per cent agar gel containing calcium chloride is added a solution of sodium carbonate. The calcium carbonate formed by the interaction is deposited in strata throughout the agar cylinder (vide Hatschek, "An introduction to the physics and chemistry of colloids," p. 73, P. Blakiston's Son & Co., 1919).

segregation in the future Q-disc, must be considered to cause the assumption of an ellipsoidal form of the colloidal particles with the long axis parallel to the length of the sarcostyle. Such original elongation of the colloidal particles may cause a certain amount of elongation or longitudinal growth of the prefunctional sarcostyle. A possible original change of form, under the influence of the entering crystalloids, from an ellipsoidal form (with long axis of colloidal particle parallel to length of fiber) to a spherical shape, would offer the same basis for a future contraction of the sarcomere, if we assume that the formation of the contraction band involves a change of form of the colloidal particles (due to alteration of surface tension) from a spheriodal form to an ellipsoidal form in which the long axis of the colloidal particle is placed at right angles to the long axis of the sarcostyle. All things considered, however, the former alternative seems the more probable.

We may now proceed to consider contraction in the histologically mature sarcostyle. Contraction is initiated by a nervous stimulus. The latter may be regarded as a wave of negative electricity. We may suppose that the negative charge enters the sarcomere at the level of the more delicate mesophragma. This disturbs the electrical potential and causes repulsion of the electrolytes; that is, the charged ions are made to travel from the level of the mesophragma through the adjacent colloidal area against the telophragmata, where contraction bands are formed. The movement of the electrolytes among the colloidal particles causes a change of surface energy, hence of surface tension, by reason of the discharge of surface electrical charges and in consequence a change of shape of the colloidal particles. If we assume that this change of shape is one of change from an ellipsoidal form (oriented in the longitudinal plane) to a spheroidal shape, the shortening and thickening of the constituent sarcomeres of the sarcostyles, and thus muscle contraction, is accounted for. The formation of the contraction band again results in a condition of stable electrical equilibrium, which latter is again upset when the particular nervous stimulus is interrupted, and a movement of the electrolytes is started in the opposite direction, resulting thus in the characteristic strati-

fication and the electrically stable condition of the sarcostyle in repose. If this is in fact the central significance of the deeply staining Q-substance, its variable relative width in different fibers of the same muscle becomes intelligible: its relative quantity within certain limits may not be a fundamentally essential requirement for adequate function of the contractile mechanism; all that may be required is a certain minimal amount and limitation within certain maximal amounts. Furthermore, the apparent relative amount of the Q-substance may be largely incidental to the degree of its concentration.

Since I have previously deduced and supported the hypothesis that intercalated discs, characteristic of heart muscle, and occasionally found also under certain conditions in voluntary striped muscle,[7] represent in essence modified irreversible contraction bands, it seems demanded in this connection that the formation of these intercalated discs be also explained consistently with the above outline of muscle contraction. During muscle contraction lactic acid is formed. When a muscle is made to function to exhaustion, the amount of lactic acid is excessively increased. Acid has a precipitation or coagulative effect upon colloids and upon mixtures of colloids and crystalloids. Intercalated discs would thus find their explanation, in accordance with the above scheme of contraction, in the supposition of the production of a relatively excessive amount of lactic acid under certain conditions, sufficient to effect a precipitation, that is, an irreversible coagulation, of a part of, or an entire contraction band.

The above-outlined physicochemical explanation of muscle contraction is in essence very similar to that presented by Prenant, Bouin, and Maillard.[14] These histologists describe contraction as an electrocapillary phenomenon. The cause of the shortening and thickening of the sarcomeres they also locate in a change of shape of the ultimate colloidal particles of the intrafibril sarcoplasm, following an alteration of electrical potential of opposite surfaces of contact of adjacent particles. But these authors do not carry their analysis and interpretation to the point above indicated with regard to the first appearance and the segregation of the crystalloids within the primitive colloidal

sarcomere, nor do they recognize a movement of crystalloids during contraction from the mesophragma to the telophragma, nor do they locate the cause of change of shape of colloidal particles specifically in the surface of contact between electrolytes and colloidal particles.

Similarly Lillie's[10] explanation of muscle contraction has a close resemblance to our hypothesis. However, Lillie conceives of the intimate structure of the sarcomeres in our opinion erroneously, in that he regards the dim Q-disc as the result solely of a greater concentration, or of a different state of aggregation, of colloidal particles at this level. This alleged constitution presupposes relatively large interstitial fluid-containing spaces in the clear J-disc. Nor does Lillie recognize a movement of dim substance during contraction. He does, however, assume a movement of interstitial fluid from *M* to *Z*, but only as an incidental result of the closer aggregation of the colloidal 'submicrons' of the dim disc. Lillie conceives of the energy of contraction as transformed surface energy of the ultimate structural element or colloidal particle (submicron) composing the fibril gel. The shortening and thickening of the sarcomere is thought to result from the massing of the colloidal particles in the 'anisotropic' segments, the massing itself resulting from the heightened surface tension resulting from diminished electrical surface polarization. He regards contraction as similar to reversible coagulation of colloids. This hypothesis, considered in detail, gives no clue for the consistent interpretation of intercalated discs. It is readily conceivable that the conditions here postulated might lead to an irreversible coagulation of sarcoplasmic colloids; but such areas of irreversibly coagulated sarcoplasm would be at the level of the mesophragma, according to Lillie's explanation, and not, as is actually the case, at the levels of the telophragmata.

According to our hypothesis, on the contrary, the shortening and thickening of the sarcomere, that is, contraction, results from the change of shape of the ultimate colloidal sarcoplasmic particles following an increased surface tension, the latter resulting from decrease or disappearance of the surface charges of the

colloidal particles accompanying the movement of electrolytes among them from the mesophragma to the telophragma, the movement being initiated by the disturbance of electrical potential of the membranes, primarily of the mesophragma, surrounding the sarcomere following the passage of nerve stimulus. It must be admitted, however, that a precipitation of colloidal particles by electrolytes would have essentially the same effect of shortening and thickening of the sarcomere as would a change of shape of the particles. But Lillie's hypothesis permits of no plausible explanation of the dim character of the contraction band. If, as Lillie assumes, the Q-disc of the fibril in repose is 'dim' because of a closer aggregation of colloidal particles at this level, and if, as he further assumes, contraction is essentially a matter of a still closer massing of colloidal particles at this level, with a forcing of interstitial fluid into the telophragma borders of the clearer J-segments of the sarcomeres, then the latter areas should become lighter instead of becoming darker, as they actually do become as parts of contraction bands. If the Q-discs are 'dim' because of a closer aggregation of colloidal particles here, then the 'dimness' of the contraction bands should consistently be explained in the same way; but that the latter are areas of closer aggregation of colloidal particles is in contradiction to the central idea in Lillie's hypothesis. Reconciliation of this damaging contradiction can be effected, and the integrity of Lillie's hypothesis maintained, only on the assumption that the Q-disc is dim because of the presence here of an additional darker, more fluid substance, which latter becomes forced against the telophragmata during contraction and here gives the darker color or 'dim' appearance also to the resulting contraction band. But when this further assumption has been added to the basic assumptions of Lillie's hypothesis, we are very close to the hypothesis here urged and supported, namely, that the cause of contraction is located in the final analysis in the fact of a movement of 'dim' substance among the colloidal particles of the sarcomere from *M* to *Z*. And in view of the demonstration of the segregation of crystalloids in the dim discs (Q-disc and the contraction band) the latter hypothesis would seem to be the most satisfactory alternative.

No hypothesis of muscle contraction can of course be satisfactory that cannot be harmonized with the principle of the conservation of energy. We must be able to find within the muscle, sources of energy approximately equal in sum to the amount of energy expended by the functioning muscle; which energies must both be approximately equal to the underlying chemical energy of the metabolic processes of active muscle. The details of the exact relation between the chemical energy of muscle metabolism and the postulated surface-tension energy of the sarcoplasmic particles need not be here considered. The energy of the nerve stimulus need of course be only sufficient to start the initial link in the chain of chemical reactions of the metabolic processes underlying the assumed surface-tension energy of contraction. Lillie[1] supports the hypothesis that the contractile energy of muscle is due to changes in surface tension of certain muscle elements by these statements:

> In contraction the surface tension of these elements is supposedly increased. If this increase of tension is sufficiently great, and the area of the active surface sufficiently large, the transformable surface-energy, which is measured by the product of these two factors, may be sufficient to account for the work done by the muscle in contraction. . . . . There is . . . . . good reason to regard the ultimate colloidal particles of the fibrils as corresponding to such elements. By their union to form larger particles, as in the general process of colloid-coagulation, sufficient mechanical energy to account for contraction might conceivably be freed, since the reduction of surface-area in such a process may be very great, implying a correspondingly large transformation of surface-energy (p. 252).[2]

In résumé, the gist of our hypothesis involves the following assumptions, which are consistent with the fact of a movement of 'dim' substance from the Q-disc to the contraction band during contraction: The nerve stimulus causes a movement of ions from *M* to *Z* effecting a change in shape of the colloidal particles from ellipsoidal to spherical; cessation of stimulus, an instant return of ions from *Z* to *M* with a return to the original ellipsoidal form of the colloidal particle; the change in form of the

[2] For a review of the earlier literature touching similar interpretations of muscle contraction, the reader is referred to Lillie's paper and to Schaefer's textbook (p. 189).

latter being the result of an alteration of surface tension following alternating increase and decrease of surface electrical charges under the influence of the reversal of the direction of the current of action and the moving electrolytes.

The histologic data relative to the intimate structural changes in contracting muscle above given seem in strict accord with the conclusion that the source of the contracting energy of muscle resides in alterations of surface tension in the colloidal particles of the ultimate muscle fibrils. My conception of the physicochemical process in ultimate detail differs from that of Lillie in essence only in that Lillie interprets contraction as the result of an aggregation or union (resembling reversible coagulation or precipitation) of the colloidal particles mainly in the Q-disc, with expression of interstitial fluid into the J-disc, following increase of surface tension due to decrease of surface electrical charges; while I view the histologic data (supplemented by the microchemical data of Macallum and of Menten) as indicating an actual movement of soluble crystalloids (electrolytes) from the mesophragma to the telophragmata, which movement of electrolytes may be interpreted as the chief factor in effecting an increase of surface tension of the colloidal particles and so altering the shape of the particles, which alteration of shape, rather than a massing of the particles, effects a shortening and thickening of the sarcomeres.

SUMMARY

1. The relatively very coarse sarcostyle of the wing muscle of the wasp is strictly homologous with the myofibril of vertebrate striped muscle. Both varieties of fibrils consist of bundles of extremely minute constituent metafibrils. The wasp's sarcostyle has an enveloping layer with the properties of an osmotic membrane, the sarcostylic membrane.

2. The structural changes exhibited by a striped muscle fiber during contraction are the result of similar changes in the constituent metafibrils. The fundamental and essential change con-

cerns the equal division at the level of the mesophragma, and the subsequent movement, of the more deeply staining substance of the Q-disc, against the terminal telophragmata of the sarcomere, where are formed the contraction bands.

3. The salient histogenetic steps occur in the following order: The myoblasts of the imaginal disc differentiate from ectoderm; the first-formed myofibrils are homogeneous; the telophragmata precede the appearance of the Q-discs; the latter are at first very delicate and only gradually acquire their typical definitive width. The sarcosomes appear only relatively late, shortly before functional activity of the wings.

4. The order of development of the two chief cross-stripes, the connecting Z-membranes and the Q-discs, explains the exact horizontal alinement of similarly modified levels of the constituent fibrils of a striped muscle fiber. The telophragmata probably function chiefly as the pathways along which the deeply staining substance of the Q-discs first enter the sarcostyle, and along which metabolic products pass to and fro between the sarcostyles and the interfiber tissue spaces.

5. In the effort to disclose the ultimate physicochemical bases of muscle contraction, we may legitimately and confidently confine ourselves to the structure of the sarcomere of the relatively coarse myofibril (sarcostyle) of the wasp's wing muscle. The fundamental factor in muscle contraction is located in the movement of the deeply staining substance of the Q-disc against the telophragmata in the formation of contraction bands. The concomitant shortening and thickening of the sarcomeres is interpreted as the result of a change in shape, from ellipsoidal to spherical form of the ultimate colloidal particles of the intrafibril sarcoplasm, following an increase of surface tension of these particles (submicrons) resulting from a decrease of surface electrical charges due to the passage of electrolytes (crystalloids of the deeply staining substance of Q) among the colloidal particles.

EXPLANATION OF FIGURES

The drawings were made from sections of tissue fixed in 10 per cent formalin. The sections were cut at 4μ, and stained with iron-hematoxylin. With the exception of figure 13, the magnification of the drawings is 1300 diameters. The section from which figure 10 was made was lightly counterstained with eosin.

PLATE 1

EXPLANATION OF FIGURES

1 *a*. Longitudinal section of myoblast immediately after separation from the imaginal disc. The originally single nucleolus has become divided in anticipation of the ensuing direct division of the nucleus. *b*, Three slightly older, now multinucleated myoblasts, in process of fusion to form a muscle fiber. Delicate peripheral myofibrils are faintly discernible. The specimen from which these drawings were made was at the latest larval or earliest pupal stage; wing pads were present, but the legs had not yet appeared.

2 *a*, *b* and *c*. Transverse sections of three successively older myoblasts from the same specimen as figure 1. Sections *a* and *b* correspond to *a* and *b* of figure 1; *c* represents a slightly older stage, cut at the level of lateral fusion as indicated by the two radially adjacent nuclei. *c.t.*, an interfiber connective-tissue cell in early stage of metamorphosis into a fat-cell.

3 Transverse section of later wing-muscle fiber from same specimen. The nuclei are now very numerous and scattered apparently at random. The myofibrils are uniformly distributed throughout the sarcoplasm and appear as darker dots in transverse sections. *c.t.*, a connective-tissue cell. The latter are very numerous and completely fill the wide interfiber spaces.

4 Longitudinal section of fiber like the one of figure 3. The homogeneous myofibrils are conspicuous between the columns of nuclei. The interfiber spaces are approximately of the width of the diameter of the fibers. These spaces are completely filled with short fusiform and polyhedral connective-tissue cells.

5 Transverse section of older fiber, from white pupa (with wings and legs). The fibrils have become much coarser and appear radially disposed along the left border.

PLATE 2

EXPLANATION OF FIGURES

6 Longitudinal section of fiber like that of fig. 5. The nuclei are long narrow elements dividing directly into smaller nuclei. Among the homogeneous coarse myofibrils are scattered smaller irregular granules. There is as yet no indication of telophragmata or other stratification in the fibrils.

7 Peripheral portion of older fiber in transverse section, showing the coarse myofibrils (sarcostyles), a peripheral nucleus, and the sarcolemma. Sarcosomes have not yet made their appearance. The section is of a later pupal stage (gray pupa).

8 Portion of adult wing-muscle fiber in transverse section, showing the coarser myofibrils and six included irregular sarcosomes.

9 *a*, *b*, *c*, *d* and *e*. Three successive stages in the later development of the myofibril, from a longitudinal section of the thoracic (wing) muscles of a gray pupa (same as fig. 7). *a* shows two adjacent fibrils in which only the Z stripe (telophragma) has appeared. This stripe stains very intensely at this stage. In fibril *b* the Z-stripe is faint, and a deeply staining but thin Q-disc has appeared. In *c* the Q-disc has become much thicker. *d* and *e* are at the same stage of development, but in *d* the Q-disc has become bisected and an H-disc has in consequence appeared, and in *e* the metafibrillar constituent elements of the sarcostyle have become conspicuous.

10 Longitudinal section through region of attachment of muscle to epidermis. The nucleus lies in the 'tendinous' portion of this connection. This tendinous portion stains much more deeply in a very dilute eosin counterstain than the muscle. At the levels where the sarcostyles break up into the 'tendon fibrils' the telphragmata disappear.

11 Small area of longitudinal section of wing-muscle sarcostyles of older (black) pupa. Between the sarcostyles are single rows of small oval sarcosomes, generally two to a sarcomeric interval.

12 Portion of a transverse section of a fiber like that of figure 11, including one nucleus. Many of the apparently oval sarcosomes are now seen to have lateral wing-like processes. Compare with figures 7 and 8.

13 Sarcostyles of definitive wing muscle of adult wasp at four successive stages in contraction. Fibril *a* is in repose; *b* is in an early, *c* in a later stage of contraction; *d* represents a contracted fibril with almost fully formed, double contraction band.

Resumen por la autora, Kaethe Weller Dewey,
Universidad de Illinois.

Contribución al estudio del sistema linfático del ojo.

La autora considera a la coloración vital como el mejor medio para demonstrar los capilares linfáticos y espacios linfáticos del ojo, del mismo modo que los de otras partes del cuerpo. Las células endoteliales que tapizan estos canales tienen la propiedad de teñirse con el colorante vital. Los resultados de los experimentos con la parafenilendiamina hacen resaltar las diferencias entre los espacios de los tejidos y los espacios linfáticos, el plasma y la linfa propiament edicha. Las observaciones llevadas a cabo mediante el teñido vital con referencia a su significación presunta en el sistema linfático no están en contradicción con los hechos anatómicos reconocidos. Aceptando el hecho de que las células endoteliales vitalmente teñidas denotan la presencia de canales linfáticos, se comprueba la ausencia de dichos canales en la córnea, mientras que la conjuntiva los posee abundantes. La esclerótica posee muy pocos capilares linfáticos, que a veces faltan en absoluto; pueden acompañar a los vasos sanguíneos que la atraviesan. Tampoco existen en la retina. La coroides los presenta principalmente en los coriocapilares. La glándula lagrimal, el tejido orbitario y los párpados presentan abundantes capilares linfáticos. No existen en el cartílago tarsal de los párpados. Las células vitalmente teñidas son mas abundantes en el cuerpo ciliar y, especialmente, en los procesos ciliares, que en cualquier otro parte del ojo. Esto coincide probablemente con mayores actividades funcionales, tales como la intensa participación en la secrección del fluido intraocular. El iris está provisto de escasos capilares linfáticos, a pesar de su rica irrigación sanguínea. Esto indica que tal órgano no desempeñá las mismas actividades funcionales que el cuerpo ciliar.

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED
BY THE BIBLIOGRAPHIC SERVICE, MAY 24

A CONTRIBUTION TO THE STUDY OF THE LYMPHATIC SYSTEM OF THE EYE

KAETHE W. DEWEY

Research Laboratory of the College of Dentistry, University of Illinois

THREE FIGURES

In view of the great interest which evidences of an etiological relationship between infectious processes about the teeth and pathological conditions in other regions are receiving in recent years, clinical and anatomical investigations vie with one another in furnishing the necessary scientific foundation for more or less empirical conclusions. Relations between certain affections of the eye and diseased teeth have been recognized since the remotest ages, but reliable reports of actually observed transmissions of pathological processes from the teeth to the eye are all of a relatively late date. The number of these published reports is not inconsiderable.[1] Little, however, is yet known concerning the routes of transmission that could in any way be considered as positive and final. The dental origin of cases of the so-called dental eye fistula, orbital phlegmon, and abscesses is revealed chiefly through the fact that the eye conditions either promptly disappeared with treatment of the involved teeth or that they developed upon the extraction of a tooth with or without involvement of the maxillary sinus. The traveling of the pus from diseased teeth to the orbit, as, for example, in phlegmon, has often been represented as being per continuitatem along the outer surface of the maxilla over the orbital border. Frequently a transmission by way of the veins is assumed, and also a few casual suggestions occur in the literature that the processes may progress by way of the lymphatics. The latter route, however, is probably more important and much more frequent than the

[1] A report of clinical observations along these lines will be published in Archives of Ophthalmology, July, entitled "Affections of the Eye from Diseased Teeth."

scanty and incomplete statements concerning it would make us believe.

The demonstration of direct communications between the lymph supply of the dental region and that of the eye is obviously difficult. In previous experimental work for the demonstration of the lymphatics of the dental pulp and the peridental membrane[1,2] indications of extensive anastomoses in the lymph-supply of these two regions were sometimes incidentally obtained. In injections by the Gerota method of Prussian blue into the gum tissue the fluid was not only forced through the bony tissue of the jaw into lymph-vessels of the peridental membrane, but sometimes deep and superficial lymph-vessels of the infraorbital region were also injected. The looseness of the orbital tissue makes injections in the region of the eye unsuitable for purposes along these lines: the injection mass will follow the direction of the least resistance and fill the loose tissue of the orbit. This occurs also in injecting the fluid through the infraorbital foramen, which is the most accessible place for reaching lymph-vessels in either direction to the eye as well as the dental region.

Until recently our knowledge of the lymph-supply of the eye region was very limited and it is still quite incomplete with regard to the lymphatic system of the eye proper. Bartels,[3] in 1909, writes: "Nowhere besides in the lids and the conjunctivae have genuine lymph-vessels been surely demonstrated, while we may say that it has been shown with a probability bordering on certainty, that in the cornea, the lens, and the vitreous body they are completely lacking. In fact, we need not look for a current of fluid in a stable optic apparatus. It is quite different, however, in the other parts of the eye which constantly have to perform most important work and where therefore correspondingly active metabolic interchanges must be assumed a priori. They have not yet been demonstrated, however."

A lymphatic apparatus of the orbit has been demonstrated by Birch-Hirschfeld.[4] That the existence of such a system may be presupposed has been claimed before him by some writers who are unwilling to consider the lymphangiomas of the orbit as heteroplastic formations; the occurrence of these speaks for the

presence of lymphoid tissue in the orbit even if in such minute amounts as to escape microscopical observation. By methods which, according to Birch-Hirschfeld, produce an increased lymph secretion or lymph stasis resulting in dilatation of the lymph-capillaries, this author believes he has seen distinct lymph spaces in the orbital tissue—in the lipoid tissue, the lacrimal gland, between the muscles, and in the neighborhood of the optic nerve and the periosteum. With his methods he could not demonstrate the direction in which the lymph flows off nor a connection with any lymph-gland. He believes, however, we may assume that communication exists between these spaces and the lymph-vessels of the nose, and that there is a connection between the orbital lymph system and that of the surrounding regions through the perivascular spaces about the vessels passing through the superior and inferior orbital fissures.

Histologically, the demonstration of the minute lymph-vessels of most organs is very difficult, if not altogether impossible. Post-mortem, they are practically virtual spaces and the endothelial cells lining them are in general indistinguishable from the slender nuclei of the surrounding connective-tissue cells. In order to distend them and thereby render them more amenable to microscopic study Birch-Hirschfeld employed a drug which is known in pharmacology and toxicology to produce chemosis and edema of the orbit, exophthalmus and increase of the intra-ocular pressure. This drug is paraphenylendiamine hydrochloride. He also made use of dionin, small pieces of which he introduced into the orbital tissue. The action of this drug is to cause dilatation of the capillaries and increase of the lymph excretion, and this is especially well demonstrated about the eye. Paraphenylendiamine, according to him, produces stasis of the lymph, and an increase of the secretion of the lacrimal gland, of the mucous secretion of the conjunctiva and the salivary glands. If a large dose is given, the edema of the orbit extends also to the face and the neck. Edema of the glottis is the final cause of death. Similar observations are reported by Grunert,[5] Matsumoto,[6] Puppe.[7] The spaces in the orbital tissue and those in the lacrimal gland which Birch-Hirschfeld found dilated and filled

with fluid after diamine poisoning are believed by him to be lymph-spaces, and he states that in some of the larger and medium-sized spaces he found a distinct endothelial membrane.

These statements by Birch-Hirschfeld seemed to me of extreme importance. If the observations could be verified and his conclusions shown to be right, the use of paraphenylendiamine should enable me to prove the correctness of a view obtained from previous experimental work on vital staining, which, in the absence of more positive proofs, I could express only suggestively.[8] Vital staining, I stated, may be the means of demonstrating the lymph-channels of origin in most organs of the body by exhibiting their endothelial cells which have an affinity for vital stains. Granting the correctness of Birch-Hirschfeld's observations, paraphenylendiamine should be a valuable aid in such investigations by demonstrating a lumen in such endothelial-clad lymph-channels.

I tested this drug on two dogs, two cats, ten rabbits, and ten frogs. The larger number of these animals were injected with lithium carmine previous to their treatment with the diamine poison. The results of these experiments will be reported in detail in another paper as a question dealing largely with pharmacology. They were disappointing to the extent that they contributed nothing to the main purpose of this study: the microscopical study of the tissues in diamine poisoning failed to reveal what I had expected to find. The dilated spaces in the edematous tissues are not lined with vitally stained endothelial cells. Most of them are simply surrounded by delicate fibers without any cellular elements; occasionally a slender nucleus may be seen in this wall, resembling as much the nucleus of a connective-tissue cell as that of a flat endothelial cell. Vitally stained cells may be seen near these spaces, but never so near as to justify the impression that they form any part of the wall. I am, however, not inclined to believe that these spaces are lymph-spaces, as Birch-Hirschfeld does, but consider them simply as tissue spaces and distended meshes in the connective tissue, nor do I regard the fluid as lymph proper, but as a serous effusion, plasma from the blood-vessels.

Sections from the edematous subcutaneous tissue of the face and over the lower jaw in rabbits show that all this tissue is split up into innumerable spaces and slits filled with fluid, to regard all of which as lymph-spaces, potential or actual, would not be reasonable. One of the chief effects of the drug seems to be on the blood-vessels, perhaps irritating the endothelial wall of the capillaries, and thereby rendering it more permeable. This is particularly noticeable in muscles of the eye. The bundles and fibers of the muscles are separated more than is normal; the fibers of the connective tissue in these intermuscular spaces are slit apart and all these widened meshes and spaces are filled with fluid, which stains well with hematoxylin. The muscles are richly supplied with blood-capillaries which wind in and out about the muscle fibers. But we fail to see any lymph-capillaries with a perceptible lumen; if they are present, as is to be presumed, they are at any rate not dilated. The muscles about the eye, like some muscles of the face, show a brown discoloration after diamine poisoning. It is an interesting observation that, while the anatomical and clinical effects of paraphenylendiamine are so widely different in the different species of animals, and even in animals of the same species, they all have one feature in common, viz., this brown discoloration of certain muscles of the face. Some of the writers who have studied the effect of this drug claim that the cause of the edema is to be sought for in the lacrimal gland. On the other hand, Puppe believes that the stasis edema is perhaps due to the formation of thrombi in the veins, and Kunkel[9] also assigns to the blood-vessels and the blood a greater significance for the development of the intoxication edema. My observations agree with the latter view.

On account of the extensive anastomoses of lymph-vessels obstruction to the outflow of lymph does not readily occur. We may conceive of the action of paraphenylendiamine as follows: in subcutaneous injections the drug enters the lymph channels, thence it is carried into the blood, where it irritates the walls of the blood-vessels, possibly having an injurious effect on the endothelial cells of the capillaries. Transudation of the plasma occurs very rapidly, the fluid filling all the tissue spaces and sep-

arating the tissue elements. The function of the endothelial cells of the lymph-capillaries being not simply one of absorption of such free fluid, but probably one of a selective action, of an interaction of metabolic processes, the fluid is not taken up and carried off rapidly enough with the result that stasis-edema develops.

The formation of lymph is not, as was formerly believed, a mechanical process, i.e., one of simple filtration and diffusion, but is work essentially done by the organs themselves. The mechanical theory has been superseded by the cellular-physiological theory. The endothelial cells of the lymph-capillaries probably play a chief part in these processes. Although these capillaries end or begin as absolutely closed culs-de-sac, and the presence of a continuous endothelium represents a barrier between them and the surrounding connective tissue, "the relations between the vascular cavity and the connective-tissue spaces remain very close," as Delamere[10] states, "and cellular immigration and osmotic exchanges may always take place and the capillaries fulfill their function of drains, and, if the observations of Renaut are confirmed, may even act as selective drains."

The value of paraphenylendiamine in conjunction with vital staining is, in my opinion, this, that it illustrates and supports the theory of a difference between spaces filled with tissue fluids and real lymph-spaces and lymph-capillaries, which constitute the channels of origin of the lymph system. Bartels,[3] it is true, is rather skeptical as to any fruitful research along these lines. To him this much-debated question is largely a philosophical one; he writes: "The question concerning the origin of the lymph system and the development of the lymph stream from the flow of the tissue juices is a purely philosophical and not an anatomical one. This question and that of the endings of the blood-vessels should be eliminated from anatomical discussions." Nevertheless, the contemporary conception of the origin of the lymph system is emphatic in upholding the theory of an independence of the lymph-spaces and the tissue spaces, and of the absence of open communications between them, as also of a difference between plasma from the blood-capillaries and lymph proper.

This fact is also illustrated by the observation that injections into the submucous cellular tissue of the skin may fill the tissue clefts and tissue spaces and produce edema, but not fill the lymph-vessels. Similar observations may be made in injecting the blood-vessels with carmine gelatin; when the injection is continued under high pressure for some time, it may happen that the fluid portion of the injection mass is pressed through the stretched capillary wall and fills the tissue spaces producing edema without entering into lymph-vessels. In fact, I have never been able to fill lymph-vessels by way of the blood-vessels.

As a result of my observations from the experiments which I have made, I have come to the conclusion that the vitally stained cells within the connective tissue of organs represent the endothelial cells lining the capillaries of origin. By several writers the view has been expressed that the connective tissue evidently plays a much more important rôle than that of being simply a supporting stroma for other parenchymatous tissue, and this impression is imparted to them chiefly by the presence of these peculiar vitally staining cells which have been called rhagiocrines, resting wandering cells, macrophages, pyrrol cells, histiogenic wandering cells, etc. The ability of these cells to take up the vital stain apparently coincides with specific functional properties; they have chiefly been alleged with secretory functions, and Renaut[11] writes of the connective tissue as "the largest of the glands with an internal secretion which exists in the body of vertebras." On the other hand, Ehrlich points out the extraordinary adaptability of the cellular elements of this tissue and that a specific modification adjusted to definite functions of the organ which it supports, cannot be considered as in any way astonishing. But nowhere in the literature have I found even a suggestion that these specific cells may belong to the lymphatic apparatus. Yet we know that everywhere in the body the structures which constitute the beginning of the lymph system are embedded within the connective tissue. It is only reasonable to assume that the endothelial cells which form the sole wall of these delicate primary lymph-channels (lymph-spaces and lymph-capillaries) are more than a lining; that they are rather the chief

agents in taking up the ambient tissue fluid or plasma from the blood-capillaries after it has been altered in its contact with the cells. This process is more than one of simple filtration, or even of a selective filtration; it is a process of vital elaboration, including probably secretion and excretion. Furthermore, as the plasma differs from the lymph partially as a result of the activities of the blood-capillary endothelium, so, too, the lymph coming from these capillaries is again modified when passing through the lymph-gland; for there are distinct differences in the lymph entering the lymph-gland and that passing out of the gland. The latter shows an increase in the cellular elements; the tendency to fibrin formation and coagulation is more rapid, and the proportion of the water is diminished. This modification of the lymph is likewise the work of the endothelium of lymph-capillaries, for the lymph-vessels entering the lymph-gland break up into capillaries, thus forming a true portal lymph system. Bearing this in mind, it is most significant that this whole process of the formation of a second capillary network and of a modification of the lymph by its endothelium is signalized, as in the endothelium of the lymph-capillaries of the connective tissue, by the property of the cells to take up the vital stain. We have here, therefore, the striking phenomenon that at the source of the lymph system there are specifically functionating endothelial cells of capillaries, and that these alone have the power to take up the vital stain. This property is absent in the endothelial cells of the lymph-vessels arising from the capillaries, but is present again, and in a most marked degree, in the endothelial cells of the capillary network within the lymph-gland; these are most brilliantly stained, while the afferents and the efferents of lymph-glands have no vitally staining endothelial cells. Evans[12] also has pointed this out as a very striking phenomenon.

There are some other general observations on vital staining, agreeing well with anatomically established facts, to which I would call the attention. It is recognized that the lymphatics are unequally distributed throughout the organism, seemingly in an arbitrary fashion. The same observation is made in regard to vitally stained cells. Lymph-vessels are considered to be

absent in a few organs and tissues; these are the same organs in which these cells are lacking. They are however, present in certain regions where lymph-vessels have not yet been demonstrated because of the almost unsurmountable difficulty in injecting them, but where they may reasonably be assumed to exist.

The character of these cells has been interpreted variously; but the name of resting wandering cells seems to be the least fitting, for the most striking feature about them is the stability which characterizes their occurrence, their distribution, their arrangement, and their number. They are invariably absent or present in the same locality and invariably scanty or abundant in the same region. The constant recurrence of these features gives a strong impression that these cells are stationary and that they are part of some definite, functionating apparatus. As to the eye, the occurrence of the same unequal distribution in the various tissues is striking.

Schnaudigl[13] has studied the effect of vital staining on the eye and made observations concerning the occurrence of vitally stained cells which are on the whole in accordance with my own. They are as follows: the lens is devoid of vitally staining cells. No such cells are found in the cornea, but the conjunctival tissue overlying the corneal tissue shows such cells in large numbers. Occasionally a long, slender, vitally stained cell is seen to extend from the conjunctiva into the cornea. The sclera contains such cells in scant number; it is not quite clear whether they belong to the tissue proper or whether they accompany the vessels traversing the scleral tissue. The cells are quite numerous in the sclera and corneal conjunctiva and in great abundance in the limbus conjunctivae. The iris is very poorly provided with them; a cell is found here and there in the region toward the posterior chamber. This striking relative deficiency of the iris in vitally staining cells apparently was not noticed by Goldmann[11] who made the most extensive studies of vital staining with reference to internal and external secretions. But the statements of his findings in the eye are so brief that we hardly need discuss this difference in our observations. Assuming that these cells denote the presence of lymph-capillaries, the extreme scarcity of such

channels in an organ which is well supplied with blood-vessels is surprising, for we may admit with some of the best authorities in anatomy that lymph-vessels may be supposed to exist wherever there are blood-vessels. This unaccountable scarcity of vital staining cells in the iris is the more striking because the region which adjoins it is unusually rich in vitally staining cells, namely, the ciliary body and chiefly the ciliary processes. The cells are in proportion more plentiful here than in any other part of the eye. They are arranged along the blood-vessels, from which, however, they are always some distance removed. They are present in all the processes; they are always in abundance and they are always arranged in the same way. When the injections of the staining fluid have been continued for some time these cells are very large and the granules are very coarse; in the iris or sclera they remain small and slender, an observation to which also Schnaudigl calls the attention. This author believes that these cells have an almost dangerous affinity for the staining substance; they are very vulnerable and show the injurious effect of the dye after prolonged contact with the staining fluid. He also believes that this affinity for the dye correlates to specific functions and that these consist perhaps in more than the secretion of the aqueous humor. From the root of the ciliary processes the cells are observed to occur in small number along the subjacent inner layer of the ciliary body; the deeper region, facing the sclera, is scantily supplied with these cells and resembles the iris in this respect. In the choroid, cells are found chiefly in the choroio-capillaris. There are none in the retina. The endo- and perineural tissue contains vitally stained cells. The loose orbital tissue is relatively poor in these cells. The muscles of the eye show the cells in the interfascicular and interfibrillar tissue, generally in the neighborhood of the blood-vessels. They seem to be in closer relationship to the blood-capillaries than, for example, in the ciliary processes; they often seem to spin around the capillaries while these again wind about the muscle fibers. In the lacrimal gland they occur in the interacinous tissue and the connective tissue surrounding the glandular structures. The lids and the nictitating membrane are well supplied with them; they always

occur in the same arrangement and the same distribution. The cartilage is absolutely free from such cells.

If we are to admit the view that these cells represent the endothelium of lymph-capillaries, we recognize that these findings correspond quite well with what we actually know or may reasonably presume concerning the lymph supply of the different parts of the eye.

Until recently our knowledge of the lymphatic system of the eye as of that of the dental region was very limited. I will sum up the most essential anatomical data which enter into the frame of this study.

The most important of recent work on the lymphatics of the eye is that of Most.[15] His results showed, in brief, the following: The conjunctiva of the lids and the eyeball contain very delicate but dense networks of lymph-vessels. At the free border of the lids they pass over into those of the skin of the eyelid. The lymph-vessels from these two networks are divided into superficial and deep ones, chiefly according to whether they arise from the outer skin of the lid or from the conjunctiva; a sharp separation is not possible since both regions communicate with each other. The superficial vessels are apparently finer and less numerous; they course in front of the orbicularis muscle and in the superficial portions of the subcutaneous fatty tissue and only in the neighborhood of their regional glands do they pass into deeper regions. The deeper vessels form many anastomoses in the deep cellular tissue of the lids and then pass on peripherally behind the orbicularis muscle. The superficial as well as the deep vessels are divided into a lateral and a median set; they empty into the submaxillary lymph-glands.

The superficial lateral vessels originate chiefly in the skin of nearly the entire upper lid and about the outer half of the lower lid. Their first and chief regional gland is a typical gland situated superficially in the parotid gland at the level of the external auditory canal. From this gland vessels go to other deeper parotid lymph-glands. Only exceptionally do the superficial lymph-vessels empty directly into the deep nodes. One or two lymph-nodes situated at the lower parotid pole and belonging to

the group of the superficial cervical glands are also to be considered as regional glands, because they may receive direct afferents from those regions of the eye.

The deep lateral vessels arise in the conjunctiva of the upper lid and the outer third of the lower lid. The regional glands, besides the superficial typical parotid lymph-nodes, include one or two nodes deeply embedded within the parotid gland itself.

The superficial median vessels arise chiefly in the skin of the inner half of the lower lid and that of the inner corner of the eye. Their regional gland is one of the submaxillary lymph-glands, especially that situated mesially of the anterior facial vein. The deep median vessels arise chiefly from the conjunctiva of the inner two-thirds and from the region of the caruncula. They form frequent anastomoses in the lid and pass along the anterior facial vein to the submaxillary glands and chiefly to a gland lateral to the one mentioned before. Sometimes this one is also injected. All these lymph-vessels go secondarily to the deep cervical glands situated along the internal jugular vein, at the junction with the facial vein. A direct connection of lymph-vessels of the lids and conjunctiva with these secondary glands could not be demonstrated. Before the vessels of the lids and conjunctiva, and especially the median vessels, enter the parotid and submaxillary lymph-glands they may pass through intermediary lymph-nodes of the face (lymphoglandulae buccales sive faciales) situated along the course of the anterior facial vein.

The submaxillary lymph-glands receive also the lymph from the outer vessels of the gingiva of the upper and lower jaw, from the inner vessels of the lower jaw, and from the vessels of the peridental membrane of all teeth. No absolutely definite lines, however, can be drawn with regard to their relation to the different groups of teeth. For there are, on the one hand, variations in the number and location of the lymph-nodes themselves; on the other hand, it not infrequently happens that single lymph-vessels from a definite region pass by the regional node into which all the others enter and empty directly into a remoter lymph-node. Another reason for this irregularity is the fact that the vessels from the gingiva form plexuses in the upper and lower mucosal

fold of the vestibulum oris, from which lymph-vessels pass out into the lymph-glands.

An important path of communication between regions of the eye and the teeth is through the infra-orbital canal with its nerves, arteries, veins, and lymph-vessels. These send branches in either direction. Two small canals, the anterior and median alveolar canals, divide off directly from the infra-orbital canal and are continued as grooves within the wall of the antrum of Highmore. They transmit the corresponding nerves and blood- and lymph-vessels to the premolar, canine, and incisor teeth. The posterior alveolar canals, of which there are two or more, are continued from foramina on the infratemporal surface of the maxillary bone. They transmit the alveolar nerves and vessels to the molar teeth and also to the walls of the antrum. Within the wall of the maxillary bone all these canals form grooves rather than canals. Very little is known yet of the lymph-vessels of the accessory sinuses. Schweitzer[16] states he observed that lymph-vessels from the maxillary sinus passed out of the infra-orbital foramen and entered the submaxillary lymph-glands.

In the endless controversies concerning the identity or difference of tissue spaces and true lymph spaces it has been customary to use the investigations of the cornea of the eye as the chief basis for discussions. The corneal spaces are not recognized now as lymph spaces. These and other spaces, like Tenon's space, the suprachoroidal space, spaces in joints and tendons, the endo- and perilymphatic spaces of the ear have only a remote relationship to the lymph system; their functions differ in every case; frequently they serve only to facilitate gliding motions and displacements necessary in the movements of the eye.

The iris contains spaces filled with fluid, which communicate with the anterior chamber and with the spaces in the ligamentum pectinatum through the furrows or crypts on the anterior surface. These spaces in the iris are regarded as belonging to the lymph system.

Genuine lymph-vessels have not been demonstrated either in the choroid or the sclera. According to Sattler,[17] the veins of the vascular layer of the choroid are surrounded by perivascular

sheaths, lined with endothelial cells. Toward the capillary layer, there exists, he believes, a continuous endothelial membrane which represents the limiting membrane of the vascular layer.

There are no lymph-vessels in the retina.

It has become customary to consider the ciliary body as the main source of the intra-ocular fluid (Leber,[18] Wessely[19, 20]). Hamburger[21] ascribes also to the iris an important rôle in the function: in fact, he believes that every part of the eye participates in the secretion and resorption of the fluid. Wessely is of the opinion that it comes nearest to a transudate. It does not contain any substance which is foreign to blood-serum. There is, hence, no reason why we should not consider the process of its secretion as a filtration process. Some difficulties arise from the relatively high salt content and the involved greater osmotic pressure, a property which it shares with the lymph. The most striking difference is no doubt the low albumen content which places it, on the one hand, in a class with the cerebrospinal fluid, the amniotic fluid, and the urine excreted in the glomeruli of the kidney, and, on the other hand, makes it stand in marked contrast to the lymph. Counterpressure to transudation may be the explanation; but we are quite as well justified in supposing that the presence of a special epithelial layer which covers the vessels may be the cause of the retention of the albumen. In the eye, the epithelium of the ciliary processes and the endothelium of the iris may act as such barriers.

Schnaudigl[17] expresses the view that the vitally staining granular cells in the connective tissue of the ciliary body may be the chief agents in the secretion of the intra-ocular fluid. The epithelial cells covering the ciliary processes remain colorless in injections of trypan blue, an observation which I also made with lithium carmine. It does not seem permissible to me to assume this specific function from the mere fact that these cells have a pronounced affinity for stains. For we must bear in mind that not only do vitally staining cells practically occur throughout the body in the connective tissue, but also that invariably they are larger and more coarsely granular in definite regions of the body, for example, in the pia of the brain, where they occur in patches,

in the choroid plexus, in certain regions of the nasal apparatus. On the other hand, there are cells admittedly endowed with secretory functions, cells other than those within the connective tissue, which also have a pronounced affinity for vital stains (the epithelial cells of the choroid plexus, in the hypophysis, the thyroid gland, the syncytial cells of the placenta, the epithelial cells of the convoluted tubules of the kidney), while other cells of a similar type are not stained by trypan blue or carmine. I am more inclined to believe that, inasmuch as these particular vitally staining cells occur practically everywhere in the connective tissue, they have everywhere the same function to perform and, inasmuch as in some localities they are invariably more intensely stained, they are involved either more intensely in the same process or in another associated function. Along this line of reasoning we may also assume that the function of lymph secretion or lymph resorption is associated with the secretion of a fluid related to lymph, such as the cerebrospinal fluid, the intra-ocular fluid, or even the chyle. From this standpoint the great scarcity and smaller size of vitally staining cells in the iris would speak against the view of some writers that the iris is notably involved in the secretion of the aqueous humor, while the presence of a large number of intensely staining granular cells in the ciliary body support the more generally accepted theory that these are the main source of the intra-ocular fluid. On the other hand, there is nothing in my view of the part which the vitally staining cells play in the lymphatic apparatus that would contradict the view expressed by Hamburger that there is a more active resorption of the fluid by the iris through lymph-channels than the generally assumed venous drainage into the canal of Schlemm. The fluid has a direct entrance into the iris through the crypts and thence into the lymph-vessels. According to my observation, lymph-channels which simply convey lymph have no vitally staining endothelial cells. This might explain the curious fact that there are so few of such cells in the iris, especially in the anterior portion. As to the drainage into the canal of Schlemm, Hamburger states, that the resorption through the spaces of Fontana may also be along perivascular lymph-spaces and not by the blood-vessels.

PLATE

PLATE 1

EXPLANATION OF FIGURES

1 Retrobulbar muscle tissue, stained with hematoxylin. *a*, blood-capillary winding about a muscle fiber; *b*, vitally stained granular endothelial cell, presumably of the lining of a lymph-vessel with collapsed walls; *c*, blood-capillary with two nuclei and separated blood-corpuscles, illustrating how the walls collapse as those of the lymph-capillaries, when no corpuscular elements hold them apart.

2 Cross-section through the ciliary body, sclera, and conjunctiva. Unstained. *a*, large granular endothelial cells in the ciliary processes; *b*, smaller cells at the base of the processes; *c*, fewer slender cells in the outer third of the sclera. There are none in the inner two-thirds of the scleral tissue; *d*, numerous larger cells in the conjunctiva.

3 Longitudinal section of a ciliary process. Stained lightly with hematoxylin. *a*, epithelial cells; *b*, blood-vessels; *c*, large granula cells.

Resumen por el autor, Ralph A. Kordenat,
Universidad de Illinois.

Contaminación de los cadáveres por el Saccharomyces cerevisiae.

El crecimiento de hongos sobre los cadáveres es causa de considerable pérdida de material en los laboratorios anatómicos. El presente trabajo da a conocer la existencia de tal contaminación. Un estudio de los caracteres de los cultivos de dichos hongos, sus propiedades de coloración, morfología y experimentos sobre animales, demuestran que esta "levadura" es una variedad no patógena y saprofítica del Saccharomyces cerevisiae. Un estudio de varios germicídas y antisépticos demostró que el crecimiento de estos hongos se impide embalsamando los cadáveres con la siguiente fórmula: Glicerina, 300 cc.; formol, 400 cc.; alcohol, 1000 cc.; fenol, 90 gramos; agua, 400 cc. Primero se usó el bicloruro de mercurio (90 gramos), pero después se omitió su empleo porque forma un coágulo resistente y granular en los vasos sanguíneos, que impide la penetración completa del liquido embalsamador, y, además, por el coste de dicha substancia química. Su presencia en el cadáver no es necesaria para impedir el crecimiento del hongo. Como medida profiláctica paños mojados en la siguiente solución, con los que se envuelven los cuerpos, impiden el crecimiento de la levadura así como la desecación y endurecimiento rápidos de los músculos expuestos. La solución se compone de: Glicerina, 50 cc.; fenol, 2 gramos; alcohol, 50 cc.; agua (que se añadirá) 1000 cc.

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED
BY THE BIBLIOGRAPHIC SERVICE, MAY 21

CONTAMINATION OF CADAVERS BY SACCHAROMYCES CEREVISIAE

RALPH A. KORDENAT

Departments of Bacteriology and Anatomy, University of Illinois College of Medicine, Chicago, Illinois

TWO FIGURES

Recently the cadavers in the anatomical laboratories of the University of Illinois, College of Medicine, became covered by a moist, slimy, slightly elevated growth that has caused no small amount of trouble and annoyance. The growth is dirty gray in color, loosely adherent, and does not penetrate the deeper tissues. It has never been noticed upon the unbroken skin of the cadaver; when the skin is removed, however, the growth begins and spreads with great rapidity, making dissection of the specimen out of the question and causing great waste of material.

A quantity of this grayish substance was taken to the bacteriological laboratory for examination. Smears showed a large number of highly refractive, ovoid cells, measuring about 7μ in diameter. In addition to these, there were large numbers of bacteria, especially staphylococci.

It seemed plain that the slimy growth was largely made up of the above-mentioned ovoid cells, and cultures were therefore made in order to isolate and study them in detail.

After several attempts, pure cultures of the organism in question were obtained.

CULTURAL CHARACTERISTICS

Neutral plain agar. After twenty-four hours' incubation at 37°C. small, round, bluish-gray colonies, about the size of a pinhead were seen. Their margins were smooth and regular. After an additional twenty-four hours' incubation at room temperature

these colonies turned white in color, but did not increase in size or number.

Five per cent dextrose agar. Twenty-four-hour cultures showed a growth similar to that on plain agar. After another twenty-four hours at room temperature they were much larger and creamy white in color, becoming confluent in most cases so as to cover the entire surface of the media. The characteristic odor of 'yeast' was noticed.

Plain broth. The growth in plain broth was not profuse. There was a slight flocculent sediment at the end of twenty-four hours. The broth was slightly turbid.

Five per cent dextrose broth. The growth was similar to that in plain broth, but more pronounced; a heavy sediment and the characteristic odor of yeast.

Litmus milk. A marked acid production at the end of forty-eight hours with coagulation; the curd in most cases being completely digested, leaving a whitish turbid whey.

Gelatin stabs. Gelatin-stab cultures showed only a slight growth upon the surface, resembling that on plain agar. No liquefaction.

The organism ferments glucose with the formation of carbon dioxide and alcohol.

STAINING PROPERTIES

The organism stains fairly well with the ordinary dyes and exceptionally well by the Gram method, being strongly Gram-positive (figs. 1 and 2). When stained by Wright's stain, a well-defined blue cell membrane is seen with pale blue mitochondria and numerous vacuoles within.

MORPHOLOGY

The organisms average about 7 μ in diameter and are round to ovoid in form. In a hanging-drop preparation of a forty-eight-hour culture, a highly refractive, non-motile, double-contoured cell is seen in an active state of budding. The budding generally takes place from the long end of the ovoid cells. The younger

cells are small and more rounded in form, while the older cells, from which the budding takes place, are more elongated. There is no tendency to form mycelia.

A pure known culture of Saccharomyces cerevisiae was compared with the organism taken from the cadaver, and it was found that in every way the two resembled each other in morphology, staining properties, and in general cultural characteristics.

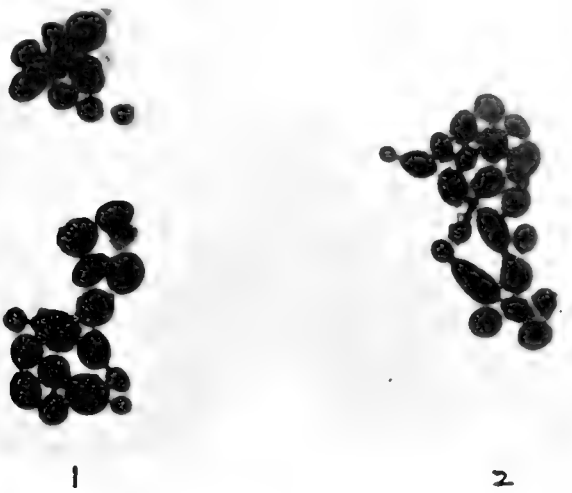

Fig. 1 Strain 'A.' Saccharomyces cerevisiae from cadaver. Gram's stain (×1200).

Fig. 2 Strain 'B.' Known pure culture of Saccharomyces cerevisiae. Gram's stain (×1200).

ANIMAL EXPERIMENTS

White mice, after being inoculated with rather large doses of a normal salt suspension of the organism, showed no ill effects.

An effort was made to reproduce the growth upon animals. Two dead rabbits, with the skin and viscera removed, were immersed in the embalming fluid used for the preparation of the bodies in the anatomical laboratories. This embalming fluid consists of—

Glycerin	300 cc.
Formalin	400 cc.
Alcohol	1000 cc.
Phenol	45 grams
Water	400 cc.

After a period of one week they were removed and a pure culture of the cadaver organism planted upon one and a pure known culture of Saccharomyces cerevisiae planted upon the other. At the end of three days the entire bodies of the two rabbits were similarly covered with a slimy, grayish film. Two days later this growth became a dirty, creamy white and resembled that found upon the cadavers. Thus, it is further evident that the two organisms are alike.

THERMAL DEATH POINT

A series of small test-tubes, each containing 2 cc. of a suspension of the cadaver culture (strain 'A') and a known strain of Saccharomyces cerevisiae (strain 'B') were used. At the different degrees of temperature indicated in the table, tubes of each of the two organisms were placed in a water-bath for a period of ten minutes, allowing one minute for the temperature of the tubes to reach that of the water-bath. The tubes were then removed and 5 per cent dextrose-agar slants inoculated and incubated. The results are given in the table. Both organisms were killed at 58°C. for ten minutes, but not at 56°C. for ten minutes.

Because of the apparent identity of the cultural characteristics and staining properties, as well as the results of the animal experiments with the organisms, it is further evident that the contamination of the cadavers is a strain of Saccharomyces cerevisiae.

I have been able to find nothing in the literature concerning the contamination of cadavers by Saccharomyces cerevisiae. In a personal communication from Dr. Irving Hardesty, of Tulane University, he states that he has had a similar experience with 'molds,' that the mold thrives on formalin-hardened bodies, that alcohol favors its growth, and that carbolic acid will not check it unless the bodies are completely immersed in the carbolic solution.

In order to find some disinfectant for this organism that might be effective in embalming fluids, the following experiments were performed:

The carbolic coefficients for potassium chromate, formalin, and mercuric bichloride were determined according to the method advocated by the U. S. P. H. S. (Hygienic Laboratory Bulletin no. 82) and further described by M. J. Rosenau in his test on "Preventive Medicine and Hygiene." Instead, however, of finding the coefficient with the use of a twenty-four hour culture of typhoid bacillus, forty-eight hour cultures of the two strains of

TABLE 1

Thermal death point

TEMPERATURE (10-MINUTE EXPOSURE)	STRAIN 'A' GROWTH	STRAIN 'B' GROWTH
°C.		
48	Positive	Positive
50	Positive	Positive
52	Positive	Positive
56	Positive	Positive
58	Negative	Negative
62	Negative	Negative
64	Negative	Negative
68	Negative	Negative
70	Negative	Negative
72	Negative	Negative
74	Negative	Negative
78	Negative	Negative

Saccharomyces cerevisiae were used, because the yeast is in its most active state of budding at that time. It was found, by determining the carbolic coefficient, that phenol is the most efficient disinfectant for these yeasts. The action of mercuric bichloride toward these organisms is too inconstant for one to reach any definite conclusion as to its use. Formalin and potassium chromate have too low a coefficient to be of any value.

The prevention of this growth was now attempted by altering the composition of the embalming fluid previously used. A rabbit was embalmed with the following fluid:

Glycerin	300 cc.
Formalin	400 cc.
Alcohol	1000 cc.
Phenol	90 grams
Mercuric bichloride	90 grams
Water	400 cc.

It will be seen that this solution differs from the one previously mentioned in that the phenol is doubled and mercuric bichloride is added. The rabbit was immersed in the same solution for three days, seeded with cultures of both yeasts, and then covered with moist towels. At the end of four days there was no growth. It was considered inadvisable to include mercuric bichloride in the embalming fluid not only because of the extra expense, but because there is a granular coagulation of the blood in the small vessels. This firm, granular coagulum completely obstructs the smaller vessels, thus preventing the thorough penetration of the solution. Other rabbits, embalmed with the same fluid minus the mercuric bichloride, were seeded with both strains of the yeast and incubated for four days. These also showed no growth.

An examination was made of the dust taken from the floor, walls, and tables of the anatomical laboratory. Some of this dust was taken up by means of a sterile cotton swab and 5 per cent dextrose broth and agar inoculated and then incubated for twenty-four hours at room temperature. Many of the samples revealed Saccharomyces cerevisiae.

As a prophylactic measure, cloth was soaked with the following solution:

Glycerin	50 cc.
Phenol	2 grams
Alcohol	50 cc.
Water (q. s. ad)	1000 cc.

and was draped over one-half of the bodies in the laboratory (group A) at the end of each dissection for a period of four months. The other half of the cadavers (group B) served as a control. During these four months none of the bodies of group A was affected, while six of the bodies of group B became covered with the growth.

By applying the above solution upon the embalmed bodies, the specimens are not only protected from the yeast but the glycerin keeps the exposed muscles more soft and pliable.

CONCLUSIONS

Because of the apparent identity of the cultural characteristics, morphology, staining properties, and of the animal experiments mentioned, it is concluded that the organism in question is a saprophytic strain of Saccharomyces cerevisiae.

The growth of Saccharomyces cerevisiae upon anatomical specimens renders them useless, thereby causing great waste of material.

Phenol is the most efficient disinfectant for this particular strain of yeast.

The contamination can be prevented by using the embalming fluids and the prophylactic measures mentioned.

The use of mercuric bichloride in embalming fluids is not practical; first, because it forms a firm granular coagulum of blood in the vessels, thus preventing the complete penetration of the fluid, and, second, because of the expense of the chemical. The prophylactic measures indicated not only protect the cadavers from the Saccharomyces cerevisiae, but prevent rapid drying and hardening of the exposed muscles.

THE ANATOMICAL RECORD, VOL. 19, NO. 3
AUGUST, 1920

Abstracted by E. D. Congdon, author.
Leland Stanford Junior University.

Simultaneous occurrence of very small sphenoid and frontal sinuses.

Because of the uncertainty as to the reason for failure or incompleteness of sinus development, the present almost unique instance of very rudimentary condition of four sinuses merits description. The sphenoid sinuses were symmetrical in form and position. They were about 4 mm. in sagittal and 14 mm. in craniocaudal diameter. A lateral extension of the cavity brought each into series with the corresponding posterior ethmoid cells. The ostium of the left sinus was so far forward and so lateral as to almost justify the interpretation that it was an ethmoid cell. The ostium region on the other side was destroyed. The cavity interpreted as the left frontal sinus was so small that it is not certain that it extended beyond the ethmoid bone. There was no especial condensation of compact bone to warrant the supposition that the sinuses may have been hindered in their development by infantile disease. It is possible that the sphenoid sinuses are to be grouped with others previously described by the writer which were apparently unable to expand through material of the concha-presphenoid fusion plane. No compensation for the loss of these cavities was noticeable in the size of the other sinuses.

SIMULTANEOUS OCCURRENCE OF VERY SMALL SPHENOID AND FRONTAL SINUSES

E. D. CONGDON

TWO FIGURES

A few very small sphenoid sinuses have been recorded, and complete absence has been claimed by several observers. Incomplete development and absence of frontal sinuses are both rather frequent. Only one previous record was found of the slight development of sinuses of two types in the same individual. This also had to do with the frontal and sphenoid cavities. They were described by Wertheim ('01) in an eight-year-old child. The observation was made for a sufficiently early stage of development to admit of the possibility that the deficiency would have been made good to a considerable degree before adult life.

The explanations which have been advanced for the absence and incomplete development of the sinuses are at present supported by little evidence. Information regarding the paranasal region needs to be collected in these cases if any explanation is to become more than a hypothesis. Although it is especially desirable that this be obtained for foetal and infantile specimens, since observations on such material will of necessity be rather infrequent, the conditions surrounding absence or incomplete development of adult sinuses should be examined for whatever information it can afford.

The rudimentary sinuses were found in the course of dissection and were preserved with the mucoperiosteum nearly intact. The subject was an adult male apparently of European parentage. The small spherical cavities were symmetrically developed and extended to the orbit behind the last posterior ethmoid cell (fig. 1). The anteroposterior diameter of the portion lying within the area usually ascribed to the sphenoid was 4 mm. and its height 14 mm. upon the right and 12 mm. upon the left side.

The ostium of the left sinus opened backward, although it was so far lateral as to be little posterior to the nearest ethmoid cell. Were it not for the position of the aperture, the sinus could as well be classified as a posterior ethmoid cell with a recess in the sphenoid bone, because the part of the cavity in series with the ethmoid cells has a position frequently occupied by one of them, and the most posterior ethmoid cell also not rarely invades the supero-anterior part of the sphenoid where the median portions of these sinuses were located.

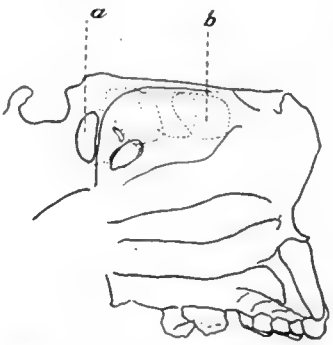

Fig. 1 Parasagittal diagrammatic drawing through left sphenoid sinus (*a*). Three posterior ethmoid cells as (*b*) represented by dash lines. A fourth, the most posterior which had been opened in dissection outlined in an unbroken line. Above it the aperture of the sphenoid sinus also shown by an unbroken line. × ½.

The portion of the wall of the right sphenoid sinus corresponding to the aperture of the left is not perforated and no communication of the sinus on this side with the nasal cavity occurs elsewhere. A saw cut has destroyed that part of the wall lying a little more medially. Either the aperture must have been situated in this region then or the sinus lacked an outlet. There has been considerable discussion as to whether this second alternative ever occurs. Some authors categorically deny that a sinus can originate without an opening, since they believe sinus formation is always by the out-pocketing of the nasal cavity. Zuckerkandl ('93) states that he has seen two sphenoid sinuses

without apertures in their bony walls. No other record of the lack of opening to the osseous wall of a sphenoid sinus was found. Evidently its absence is very rare, although closure of the aperture by the swelling of the mucosa is frequent. For this reason and because the closely similar companion sinus had an opening, it is very probable that its aperture was destroyed by the saw.

Fig. 2 Right frontal sinus (*a*). × 1.

The more rudmentary of the two frontal sinuses is shown in figure 2. There is a marked difference in the frequencies of absence of the frontal sinus as given by various authors. Onodi ('11) places it as high as 20 per cent, while Boege ('02) finds it to be only 4.9 per cent. Much of this discrepancy is probably due to different conceptions of what constitutes the earliest developmental stage of a frontal sinus as contrasted with a beginning ethmoid cell. The recess (fig. 2, *a*) is here regarded as a frontal sinus because it is already separated by a ridge from another division of the frontal recess and is in the proper position

to enlarge directly into the frontal bone. It is the passage into the frontal bone upon which the application of the term frontal to a sinus should depend, but it is usually not practicable, even if it is not impossible, to determine whether small out-pocketings of the frontal recess have passed beyond the confines of the ethmoid bone or not.

No peculiarities were observed in the other paranasal sinuses which could aid in finding the reason for the rudimentary condition of the frontal and sphenoid sinuses. The spongy bone surrounding the four sinuses was somewhat more dense than the average. It may be, therefore, that foetal or infantile disease may have brought about a condition which interfered with the enlargement of the sinuses. Onodi ('11) and Wertheim ('01) have brought together some evidence of such an occurrence. The condensation of the spongy bone was not extreme, and, since there was no atrophy of the mucosa, the argument for early disease is not convincing. Furthermore, it would be surprising that sinuses at opposite ends of the nasal cavity should be affected while the maxillary and ethmoid sinuses opening at intermediate positions are normally developed.

The explanation first suggested by Toldt ('83) for the origin of the bony plates in the sphenoid sinus and further elaborated by Cope ('17) and the writer ('19) may possibly be applicable also to the retardation of the sphenoid sinuses. Toldt regarded the planes and ridges as the remnant of material at the plane of fusion of the adjacent ossification centers of the sphenoid sinus which was able to resist the absorptive action of the periosteum during the enlargement of the sinus.

Seven sphenoid sinuses out of two hundred and forty two were found by the writer ('19) whose posterior walls corresponded in position and direction with the usual plane of fusion of conchal and presphenoid centers. This led to the suggestion that resistant material had prevented the extension of the sinus backward The two rudimentary sinuses here under discussion have posterior walls lying more anteriorly and somewhat more transversely than the usual position of the plane. It may be that in this instance a plane situated especially far anteriorly put an early stop to the backward extension of the sinuses.

The incomplete development of the two pairs of sinuses in the same individual is suggestive of a correlation between the development of the two types. The interrelation of form and size of adult sinuses seems to show that alternative correlation is a common feature of sinus development when one of two adjacent sinuses succeeds in preempting space originally open to both and thus brings about the underdevelopment of its neighbor. The suggestion has also been made that as an adaptation to keep the total sinus space up to the usual amount the underdevelopment of some sinuses might be correlated with an unusually extensive growth of others through some unknown mechanism. As far as could be found, there is no evidence for the occurrence of a growth response of this nature. If there is a correlation which explains the concurrent retardation of development of the four sinuses in the specimen which has been described, it differs in type from the relationship just referred to in that the sinuses all vary from the norm in the same direction. The retardation or absence of two frontal sinuses is so often bilateral as to be probably correlated. Less data are at hand for sphenoid sinuses, though a certain degree of correlation is probable. The retardation of development of frontal and sphenoid sinuses in the same head is so rare that its coexistence in the two types is probably a matter of chance.

Anomalous fibrous cords in the hand and the phylogeny of the flexor digitorum sublimis tendon.

The fibrous cords are evidently remnants of the ancestral short flexor muscles of the hand which are normally represented by the distal part of the flexor digitorum sublimis tendons, according to Eisler's theory. They were attached proximally on the radial sides of the bases of the proximal phalanges of the fourth and fifth digits and extended distally to bifurcate like the flexor digitorum sublimis tendons and insert on either side of the volar surface of the middle phalanx. The coexistence of the cores with normal flexor digitorum sublimis tendons apparently either contradicts this interpretation or disproves the theory. Also Bardeleben and Kajava state that the flexor digitorum sublimis tendon may exist side by side with the short musculature in certain mammals, and Fromont describes an anomaly in the human hand showing this condition. Since there are compelling reasons both from comparative anatomy and embryology for Eisler's theory, it is probable that in these apparently contradictory instances the rudiments of the short flexors split to go only in part to the sublimis tendon, while the rest was retained to form more or less perfect short superficial flexor muscles.

ANOMALOUS FIBROUS CORDS IN THE HAND AND THE PHYLOGENY OF THE FLEXOR DIGITORUM SUBLIMIS TENDON

E. D. CONGDON

TWO FIGURES

Tendon-like cords were found in one hand of an aged male subject during the course of dissection by Mr. A. F. Warren. They lie upon the volar sides of the fourth and fifth fingers of the right hand and are closely similar in form and position (fig. 1). Each extends distally from an attachment on the radial side of the base of the proximal phalanx to the volar surface of the vaginal ligaments and there bifurcates. The slips thus formed pass to the opposite sides of the middle phalanx to insert into the vaginal ligament the adjacent fascia and the border of the dorsal extensor aponeurosis. Although of a somewhat less compact structure than a tendon, they can by no means be described as mere condensations of fascia. They did not bring about any marked flexion of the digits in the cadaver, and probably did not hamper movement during life.

The muscles to which the cords seem related are the short superficial digital flexors of amphibia, reptiles, and mammals. These take origin usually upon or in the volar fascia and have insertion in part at least by a pair of slips upon the sides of the metacarpo-phalangeal joint or more distally. The cords differ from the muscles in the position of their proximal ends. Instead of passing to the palmar aponeurosis along the mid-line of the digit they are deflected to the side of the base of the proximal phalanx. The dissimilarity is not great, however, because the cords are in continuity on the phalangeal bases with slips of insertion of the palmar aponeurosis. The relationship of the cords are not like those of the lumbricales or interossei, nor are either of these muscles abnormal or lacking.

The presence of ten short digital flexors in urodele amphibians, in monotremes, and marsupials is generally accepted as sufficient reason for regarding the structures as an ancestral muscle for man and other mammals possessing the flexor digitorum sublimis muscle. As will be seen Testut and Fromont have also described the primitive short superficial flexors in the adult human hand. It can be accepted with a large degree of confidence then that the anomalies in question are actual short superficial flexor remnants.

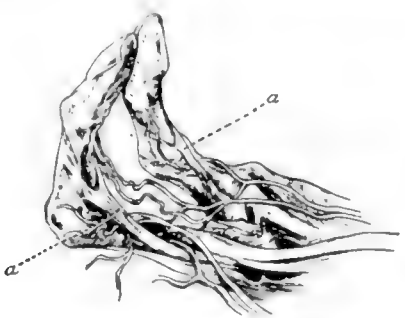

Fig. 1 Hand (after Fromont, with parts omitted) showing abnormal digital muscles. *a.a*, tendon of flexor digitorum sublimis upon which are inserted muscles (*c.c*), interpreted here as short superficial digital flexors; *b.b*, muscles interpreted as short superficial digital flexors taking the place of tendons of flexor digitorum sublimis. × ½.

The flexor digitorum sublimis muscles of man and many mammals said to arise in part from the short superficial flexor muscles lie in large part within the fore arm, but send their tendons through the palm to the digits. Here they bifurcate to insert on either side of the second phalanx. The flexor digitorum profundus, a companion muscle, whose muscle belly is also in the arm, inserts on the distal phalanges by tendons which pass between the bifurcations of the sublimis insertion. Eisler ('95) suggested that the terminal portion of the sublimis tendon with its bifurcated insertion might be nothing else than a degnerated superficial flexor muscle which after having changed completely to tendon had come, by means of its attachment to the palmar

aponeurosis, to be continuous with a part of the fore arm flexor mass which earlier inserted on the palmar aponeurosis.

McMurrich's careful study of the flexor muscles of amphibians, reptiles, and mammals ('03) gave confirmation and amplification to Eisler's suggestion. It received support of another kind when Gräfenberg ('05) found that a short flexor musculature in the hand of the human embryo connected with a fore arm mass to form a flexor sublimis.

With this view of the origin of the flexor digitorum sublimis muscle it is not to be expected that any mammalian finger will possess at the same time one of its tendons and a short superficial flexor muscle. Kajava ('11) who has examined the digital flexor musculature of monotremes and eleven species of marsupials found, as did McMurrich for other animals, that the two never occurred together in the same digit. Yet Kajava states that there are certain insectivora and carnivora which do possess both the flexor superficialis brevis and the sublimis; Bardeleben ('90) much earlier made a like claim for Hyrax and, according to Eisler (95), for Paradoxurus.

References by two authors to aberrant muscles of the human hand related to the anomaly here described bring confirmation to the theory of end-to-end fusion for the sublimis, but at the same time in part offer difficulties similar to those found by Kajava and Bardeleben. Testut is quoted by Kajava from a work which was not accessible as giving instances of the occurrence of a short flexor in the human hand for the little finger which had replaced the corresponding sublimis tendon.

Fromont found a similar displacement of the flexor sublimis in two digits of the hand. His figure is copied here (fig. 2b). A better confirmation of the theory of end-to-end fusion by a reappearance of the primitive structures could scarcely be desired. The condition of the musculature of two other digits were found however to be more involved, the flexor sublimis was present in each of them, but there were also other slender muscle bellies taking origin from the transverse carpal ligament, and inserting on the sublimis tendons (fig. 2a). The conclusion seems necessary that in these two digits part of the embryonic

rudiment derived from the ancestral short flexor have given rise to the corresponding muscles in the adult. The relationships and origin of these slender muscles are also like those of the two larger short superficial flexors. Fromont terms the two of the four short muscles which insert on the sublimis tendons superficial lumbricals, but likelihood of identity with lumbricals is excluded by their relationships and by the presence of almost normal lumbricals in the usual position in the digits to which they are related.

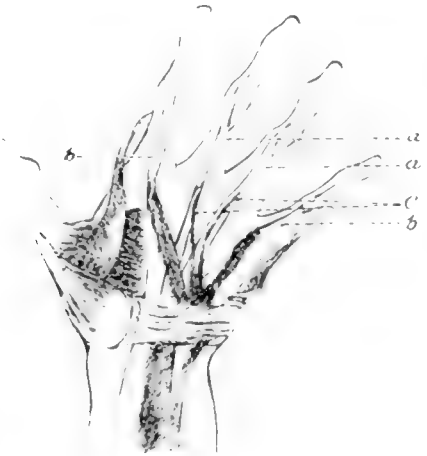

Fig. 2 Fourth and fifth digits of left hand with tendinous cords (a,a') apparently representing remnants of short superficial digital flexors. × ½.

It has been seen that the instances of abnormal human muscular development described by Testut, Fromont, and the writer confirm the comparative anatomical evidence taken from a wide field by Eisler, McMurrich, and Kajava for the theory of end-to-end fusion to the extent that they reveal a tendency toward the formation of short superficial digital flexors in man. But at the same time the anomalies of Fromont and the writer present a difficulty for the theory in the simultaneous occurrence of the short superficial flexors and the tendons which are supposed to arise from them. Observations of a like condition in the

normal structure of a few other mammals have already been referred to. A possible explanation of this contradiction is that when muscle and tendon appear together, the short flexor rudiment divided at an early developmental period to give rise to both the muscle and the tendon. The supposition that there were paired short superficial flexors in the human ancestry as in some other mammals and that their rudiments give origin one to the muscle and one to the tendon is not probable because of the rarity of the anomaly.

Acquired skeletal deformities in a young fowl.

A young cockerel reared in an incubator till about three months of age showed marked skeletal deformities which were in part mechanical effects of confinement under a roof with which the bird gradually came in contact as it increased in height. The dorsoventral thoracic diameter was reduced a half. The trunk anterior and posterior to the interacetabular line was bent downward. Apparently the down thrust of the neck against the thorax, due to the striking of the head against the roof, together with the downward pull of the leg muscles upon the posterior portion of the trunk in the effort to keep the body from falling forward were responsible for the bend. There was marked underdevelopment and further deformity of the trunk skeleton. The cervical vertebral column approached adult size, but was retarded in differentiation. The wattles, comb, and beak showed a differentiation typical of a larger cockerel. The gross appearance of the trunk skeleton suggested that the cockerel may have had rickets. No microscopic examination was made. The only indication of poor health which was noted was a ruffling of the plumage for a few days before the animal was killed.

ACQUIRED SKELETAL DEFORMITIES IN A YOUNG FOWL

E. D. CONGDON

Leland Stanford Junior University

SIX FIGURES

Two young cockerels reared in an incubator showed skeletal deformities approaching in degree the effects of a severe case of human rachitis. Although the influence of mechanical conditions upon the form of the mammalian and especially the human osseous system has long been studied, no descriptions were found in the literature of marked deformities in the domestic fowl or any other bird.

At the time when it was noticed that the chicks had been kept too long in the incubator, their backs were already in contact with the ceiling. As they grew, their heads must have been gradually forced to a lower level relative to the rest of the body.

The cockerels evidenced poor health by a ruffling of their plumage (fig. 1), and they were somewhat sluggish in their movements. There is little doubt that the direct mechanical effects due to unusual posture and contact of the head with the roof were complicated by the influence of the other unfavorable conditions, such as high temperature and lack of exercise. It may be that the slight thickening at costochondral junctions and at the posterior ends of the uncinates, the bending of certain bones and other disturbances of growth, which will be described, are due in part to rickets and osteomalacia. Insufficient attention was given to the question before the skeleton was cleaned to answer the question. Tripier[1] tried the effect of diet with low protein content and containing little earth salts upon two young pullets, and described a change in the physical properties of their

[1] Arch. de Physiol. norm. et pathol. (2) 1, 1874.

bones. He did not mention, however, any change in skeletal proportions or in the shape of the individual bones.

The larger and more deformed of the two fowl was used for a detailed examination of the skeleton. Two cockerels were chosen for comparison, one of these showed less maturity than the abnormal bird in comb, wattles, and bill, but was of nearly the same length and height. The other was chosen because the comb, wattles, and bill indicated an equal maturity. It was much larger than the abnormal fowl, though it was of average size in comparison with other normal cockerels in the same stage of development. The controls and deformed bird were all White Leghorn stock of approximately pure breed.

Figures 2 to 6 show the abnormal and the smaller control birds under equal magnification. The trunk of the abnormal cockerel is the smaller, although, as will be later seen, it would probably have been as large or larger had it developed normally. Some features of its deformity come out strikingly in the profile view with the trunk musculature in position (figs. 2 and 3). The thoracic region has a dorsal and a ventral diameter about half that of the smaller control. The posterior portion of the trunk is also somewhat smaller. A comparison of figures 2 and 4 shows that incomplete development of the breast muscle and sternal keel play a considerable part in the thoracic reduction, though the body cavity in this region is also disproportionately small in cross-section in comparison with the parts external to the trunk.

The chief skeletal malformation which can be readily traced to a mechanical cause consists of a bending downward of the anterior and posterior portions of the trunk, so that their longitudinal axes meet at a slight angle at a transverse plane passing through the hip-joint. The pelvic bones are correspondingly bent at their acetabuli and the sternum at the junction of the cartilaginous and bony portions of the keel. This condition evidently developed as an effect of the frequent down thrust of head and neck upon the thorax, when the head came in contact with the roof as the chicken tried to assume an erect posture. To retain the balance of the body upon the legs at the acetabuli,

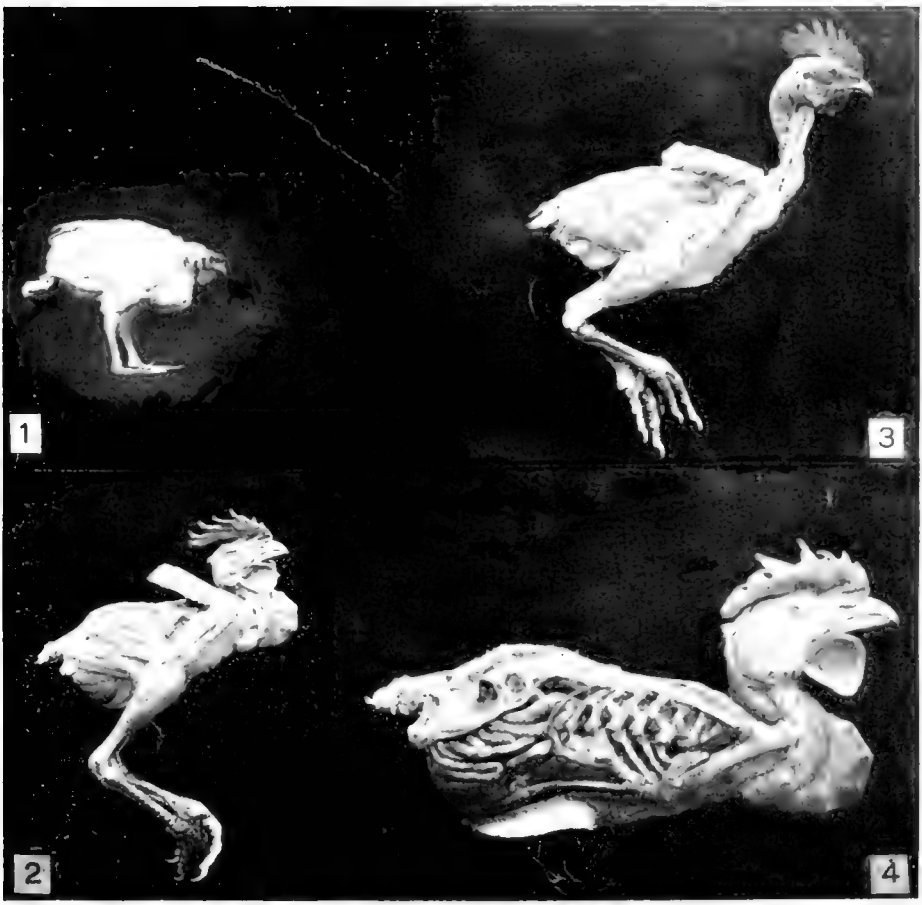

Fig. 1 Abnormal cockerel
Fig. 2 Abnormal cockerel
Fig. 3 Younger control cockerel. Magnification the same as in figure 2
Fig. 4 Abnormal cockerel.

when the downward impulse was communicated by the neck to the thorax, the musculature from the legs to the part of the pelvis posterior to the acetubular joints must have contracted with more than ordinary vigor. The two unusually powerful downward forces acting at opposite ends of the trunk resulted in the bending at the interacetabular transverse plane.

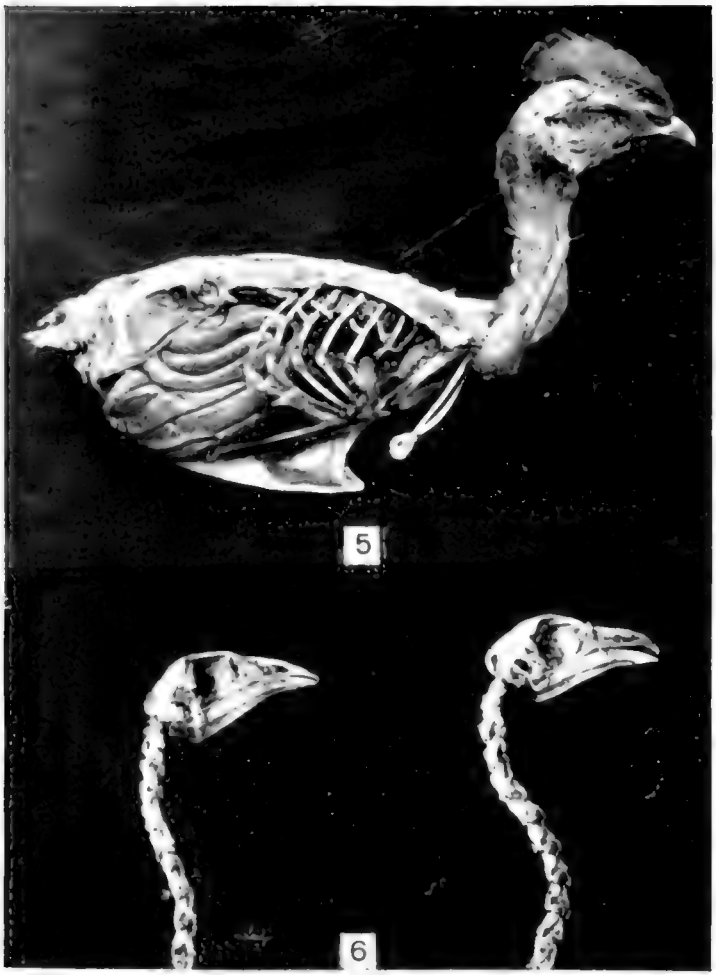
The trunk skeleton shows abnormalities throughout that may not be so directly connected with mechanical influences as is the bending of the trunk. The ribs and uncinates are thicker relative to their length than in the control birds. The ends of the costal and sternal ribs, which articulate with one another, and the posterior ends of the uncinates are enlarged. The disproportion of the trunk relative to the neck is shown in the vertebral column by a decrease in size of the successive dorsal vertebrae posterior to the second, in place of the usual increase in their dimensions.

The ossa coxae are not only bent, but are narrower than usual in conformity with the diminished diameter of the entire trunk relative to its length. The bend in the body of the sternum has already been mentioned. Its bony keel is of only half the usual dorsoventral extent at its posterior end, and decreases to an inconsiderable ridge anteriorly. The reduction of the keel is probably due in large part to the direct effect of striking the breast against the bottom of the incubator, when as frequently happened, the down thrust of the neck at the thorax caused the animal to topple forward after pushing its head against the roof. It is not probable that underdevelopment of the breast muscle had much, if anything, to do with lack of development of the keel, because other bones associated with these muscles including the coracoid furcula and body of the sternum, if of less than the usual size, are certainly much nearer to the norm than is the keel. The furcula which extends downward from the superior extremity of the coracoid to the antero-inferior angle of the keel has undergone a reduction in length corresponding to the decrease in the dorsoventral extent of the keel.

There are details in the form of the skull which may be due to the repeated striking and pressure of the head against the roof. It should be stated, however, that these do not greatly exceed in amount the normal variation as shown in the skulls of four other cockerels of about the same age. The frontal region of the skull seems to have been pushed slightly forward and down (fig. 6). The wedge-shaped projection of the cranial cavity lying between the upper and posterior portions of the orbits is enlarged at their expense, so that the orbital processes of the frontal bone are unusually conspicious in a lateral view of the skull. The anterosuperior orbital region which usually has a nearly straight edge is convex and flares upward, as though the eyeball had been pushed forward against it. A protrusion of the eyeball was not looked for while the animal was alive and it was not noticed. In the photographs of figure 2 and 4 it appears to be present. The comb is bent over as if from frequent contact with the roof, yet its deformity cannot be assigned to this cause with certainty, because lopped combs are not rare among White Leghorns.

Other gross malformations of the osseous system not directly traceable to the effects of pressure of the head against the roof manifest themselves both in the form and in the size of the bones. The ribs, uncinates, coracoid, furcula, and cervical vertebrae are thicker and more rounded than in the controls. The pelvic bones and sternum are so irregular in form that they mask any abnormality of a like nature, which may have been present. The surface markings of scapula, coracoid, furcula, sternum, cervical vertebrae, ribs, and uncinates are less sharply defined than in the control skeletons. The characteristics of form both as regards general outline and detail consist in a retention of an earlier developmental condition modified perhaps by other pathological characters.

Various parts of the skeleton show irregularities in relative volume, some of which have been already mentioned. Though the retardation of the trunk is so marked that it can scarcely be questioned, the less marked differences of relative size in



A B

FIG. 5. Younger cervical vertebral column. Magnification the same as in figure 4.

FIG. 6. *A*, Skull and portion of cervical vertebral column of younger control. *B*, Skull and upper part of cervical vertebral column of abnormal [illegible]

other regions make it difficult to decide which if any of these have normal measurements. The wattles, comb, and bill indicate maturity equal to the older control bird, whose body is twice as large as that of the abnormal cockerel, and was chosen from a number of equal maturity as representing their average size. Since the skull of the deformed bird appears to be normal except for the deformity due to pressure against the roof and is of almost the same length as the control, it may be the birds would have been of equal size as well as maturity, had conditions been normal.

The measurements of the skeleton of the extremity are unfortunately limited to the femur and the coracoid. Both agree closely in length with the smaller control. The appearance of the extremities in figures 2 and 3 confirm this view. The only careful observations of the bone form in these regions were upon the tibiofemoral joint. Here no retardation of development could be noticed.

Comparative measurements of abnormal cockerel, large and small control and rooster

	Posterior end of os coxae to anterior end of 1st thoracic vertebra	Length of skull and bill	Length of femur measured along diaphyseal axis	Average measurements of entire cervical vertebral column		
				Length of centrum	Smallest width of centrum	Interval between outer borders of articular processes
	cm.	*cm.*	*cm.*	*cm.*	*cm.*	*cm.*
Abnormal cockerel	11.5	6.7	6.7	0.98	0.62	1.24
Younger control (10 months old)	12.0	6.5	6.7	0.91	0.54	1.15
Older control (13 months old)	14.0	6.8	10.1	0.93	0.54	1.10
Rooster	20.0	8.0	13.6	1.27	0.61	1.49

The cervical column has plainly undergone an excessive development in volume, since, as seen in the accompanying table, it is not only larger than the older control in three measurements which were chosen, but it even slightly exceeds a rooster in the minimum transverse diameter of its centrum. The upper vertebrae are especially large and the atlas largest of all (fig. 6.) These facts together with the correspondence, of the limb skeleton in

length with the smaller fowl and its lack of abnormal characters lend some support to the view that the younger control may represent the true size of the deformed bird, had it developed normally and that there has been an overgrowth of skull as well as cervical vertebral column. The less sharply sculptured surface and the more massive form is found in the cervical column, which has been frequently described in other instances of overgrowth. The skull did not show a similar condition, but its comparative freedom from surface elevations would prevent easy recognition of a slight deficiency in this respect.

Notes on the branches of the aorta (arcus aortae) and the subclavian artery of the rabbit.

Although the usual number of blood-vessels arising from the aorta in the rabbit is two- a so-called innominate or brachiocephalic and the left subclavian arteries—the variation from this condition herein described indicates the possibility of a considerable departure. Of 106 specimens, about 20 per cent differed from what is usually considered normal, either in respect to the aortic vessels or the subclavian arteries of either side. In one individual a single vessel leaves the arch of the aorta, and after passing forward subsequently successively subdivided to form the left subclavian, the left common carotid, and the innominate or brachiocephalic arteries. When three vessels originate on the arch, they are usually the innominate and the two carotids, although in one case the vertebral of one side contributed to this arrangement in the place of a carotid. Several individuals show conditions suggestive of four vessels, comprising the two carotids, the left vertebral and left subclavian. The order and sequential differences of vessels from the subclavian arteries of each side are noted.

NOTES ON THE BRANCHES OF THE AORTA (ARCUS AORTAE) AND THE SUBCLAVIAN ARTERY OF THE RABBIT

FRANCIS MARSH BALDWIN

Iowa State College, Department of Zoology, Ames, Iowa

ELEVEN FIGURES (ONE PLATE)

Bensley,[1] in his Practical Anatomy of the Rabbit (p. 365), in discussing the blood-vessels of the thorax, describes the arch of the aorta as "beginning at the base of the heart, ... passes forward, and then describing a curve, in the course of which it lies slightly to the left of the median plane, turns backward along the ventral surfaces of the bodies of the thoracic vertebrae. With the exception of the coronary arteries the first branches are the large paired vessels arising from the anterior wall. They comprise the common carotid and subclavian arteries. On the right side the carotid and subclavian arise from a short common trunk, the innominate artery. The left common carotid arises immediately to the left of this vessel or from its base. The subclavian artery (a. subclavia) is the first portion of the artery of the anterior limb. It passes from its point of origin laterad to the anterior margin of the first rib, where it is replaced by the axillary artery. Near its point of origin, it gives off several branches, the relations of which are subject to considerable variation."

The large paired vessels referred to above is not exact and leads to confusion, since even in the usual condition it applies to neither the right and left common carotid arteries, nor the paired subclavian arteries, but to an innominate artery on the right side, and the left subclavian artery on the other. That the left common carotid artery usually arises immediately to the left

of the base of the innominate is perhaps correct, although in by far the greater number of rabbits dissected the origin of this vessel is well up on the mesal side of the innominate. In cases where the left common carotid artery arises to the left of the innominate, there would be three vessels arising from the cephalic curve of the aorta and not two (a pair) as above described, a condition normally found in the human. With reference to the subclavian arteries, the statement as to their branches being subject to considerable variation, is correct, but it seems important that the point should also be made, that great differences occur in these vessels on the right and left sides in the same animal.

Again, Parker and Haswell[2] describe correctly the relation of these vessels as they occur in the majority of cases, but the figure shown (p. 465) represents the condition in an abnormal individual, where the left common carotid artery originates as a branch from the arch of the aorta, and thus constitutes the third vessel from the arch, the innominate and the left subclavian being the other two. Since these discrepancies exist in the descriptions of the blood-vessels of the region in the various texts, and in view of the variability of both the arteries given off by the arch of the aorta, and their subsequent subdivisions, especially those of the subclavian, it seems of sufficient interest to record their frequency and extent. Accordingly, the following description is based upon the study of over one hundred specimens. Such records, of course, have no immediate practical value from the surgical or pathological sides, but from the educational considerations, especially from the standpoint of comparative anatomy they are rather important. No doubt the variations which are described below are to be explained in part by the persistence of foetal conditions, or in some cases by abnormalities of the vessels themselves, or to the development of extrinsic parts in their immediate region. Many of the changes brought about are probably due to different modes of transformation of the primary vessels of the branchial arches, especially the fourth, since the aorta as well as the pulmonary artery are derivatives of this arch. Again, it is well known that the heart itself originally develops high up in the neck region of mammals, and is

gradually shifted downward, so that this gradual shifting might account for some of the variations noted.

Of one hundred and six rabbits dissected* nineteen individuals showed marked variations from the usual condition, either in the branches from the aorta, or in respect to the subclavian and its branches in either side. There were others (fifteen) which showed minor variations, but which could easily be placed in some of those showing marked variations, so that their condition is represented, partially at least, in some one or in a composite of the subjoined figures.

In what may be termed the usual condition, the aorta (fig. 1, *A*), after giving off the coronary arteries close to its junction with the left ventricle, passes cephalad a short distance, and then describes a curve of a half circle and passes down the back, a little to the left of the ventral vertebrae. From the cephalic curve (arch) a comparatively large innominate or brachiocephalic artery extends upward and a little to the right and soon bifurcates, forming the left common carotid artery which passes immediately across the trachea to the left side of the neck, and a common trunk which gives rise to the right subclavian and the right common carotid arteries. A second branch from the curve of the aorta is the left subclavian artery which passes laterad and forward to branch in various ways. Usually on this side the superior intercostal (costocervical) (fig. 1, *I*) is the first branch to be given off, and passes caudomediad. Just distal in close juncture with the superior intercostal artery is the internal mammary artery, while just opposite arises the vertebral artery. Distally the subclavian artery soon divides into the transverse scapular (*T*) and the axillary (*X*) arteries. On the right side the superior intercostal and mammary arteries arise from a common trunk, as also do the vertebral and transverse scapular arteries just opposite to them. The axillary artery passes to the region of the forearm. In some cases the superficial cervical artery branches from the subclavian, but usually it is a branch of the transverse artery of either side.

* My thanks are due Mr. Ralph L. Parker, my assistant, for aid in dissection

VARIATIONS OF THE SUBCLAVIAN ARTERY OF THE LEFT SIDE

A number of interesting variations are noted in the order and sequential relationships of the various vessels arising from the left subclavian. Frequently the arteries originating from the subclavian artery in close proximity to each other so that a veritable corona of the vessels is formed. In some cases, as shown in figures 6 and 11, this takes place at quite a distance from the arch of the aorta, and can be called the long corona type, while in others, typified in figures 9 and 10 and perhaps less conspicuously in figure 8, the corona formation is closely approximated to the aortic arch. Where the corona is formed, the usual order of the vessels may be described as normal, i.e., beginning with the vertebral artery originating on the cephalomesal surface of the subclavian, the transverse scapular, axillary, mammary, and intercostal arteries followed in the cycle clockwise. In one specimen an interesting departure is noted, in that the intercostal artery (fig. 6, *I*) takes its origin from the vertebral so that there is formed in this case a very short innominate with the vertebral artery. A number of cases are observed where the intercostal and mammary arteries formed a short innominate in common as is shown in figures 4 and 7. In one rabbit (fig. 3 V) the vertebral artery of this side branches from the cephalic surface of the arch of the aorta at about its junction with the subclavian artery, and in this case it is comparatively a much larger vessel than normal. In this specimen also the transverse scapular and mammary arteries have their origin some distance cephalad, and the interval between the intercostal and mammary arteries is very noticeable. In no case is there found an innominate formed by the left subclavian and the left common carotid arteries, which of course is the typical avian condition, and which has been described to occur in most apes, and somewhat more rarely has been noted in the human. In three cases, however, varying in degrees, as shown in figures 6, 8, and 10, the left common carotid artery is a separate branch from the arch of the aorta, and in these the condition closely simulates the normal condition found in the human. In one in-

stance the points of origin of the vertebral and the transverse scapular arteries are interchanged, as shown in figure 2, and in another, figure 5, the vertebral artery arises from the laterocaudal surface of the subclavian in the same manner but distal to the intercostal and mammary arteries, and then turns mesal to enter the transverse foramina of the cervical vertebrae. In the last specimen also a number of excessory blood-vessels are noted, some of which parallel the mammary, others the intercostal arteries.

THE SUBCLAVIAN ARTERY OF THE RIGHT SIDE

The blood-vessels of this side which take their origin from the subclavian artery seem less variable in their relationships than those just described. There is the formation of what may be termed a corona in several instances, but this is with but one exception formed relatively close to the innominate, or to that portion close to the bifurcation of the innominate which forms the subclavian and right carotid arteries. Such a condition is typically shown in figure 5, where the vessels spread out in fan-shape formation about the subclavian. In one instance, the vertebral artery (fig. 2, V) originates well cephalad and on the lateral surface of the right common carotid artery, so that its displacement from its usual position is rather striking. As regards the interrelation of the intercostal and internal mammary arteries, all sorts of gradations of intervals exist from the formation of a conspicuous elongated innominate, as is indicated in figure 3, or a much-reduced innominate, as shown in figure 11, to the more or less widely separated intervals, as represented in figures 8 and 9. The intercostal artery in the last case is really a branch of the innominate, and has no connection with the subclavian. Usually the superficial cervical artery of this side as in the normal condition is a branch of the transverse scapular artery, but in two cases it is greatly displaced; one originating from the subclavian (fig. 3) and another curiously entering the common junction of the intercostal-mammary vessels, as shown in figure 10. In one case the transverse scapular artery originates as a branch of the vertebral well cephalad of the latter's

junction with the subclavian, as in figure 8, although in two other specimens this condition is barely suggested in the close proximity of the origins of the two vessels, as in figure 9.

The manner of branching of the two carotid arteries from the innominate is of interest, although not more variable than might be expected. In the majority of specimens showing differences in other respects, the two carotid arteries branch well up on the innominate. In several cases the point of origin of the left common carotid artery is close to the curve of the aorta, and in three cases (figs. 6, 8, and 10) the junction is really on the arch, thus giving rise to an additional vessel in these cases, as indicated above, which simulates very closely that found normally in the human. Three individuals (figs. 7, 9, and 10) show the formation of a thyreoid ima, so-called, a small vessel arising on the innominate between the right and left common carotid arteries, which passes forward to the thyreoid gland and gives off small vessels to the neck muscles of the region and to the trachea. Its point of origin varies somewhat in the three animals, but morphologically it bears the same position as has been described for a similar vessel in the human (McMurrich,[3] p. 511.), i.e., it passes forward from the innominate between the common carotid arteries of either side. It should be said, however, that since the common carotids of either side in man differ slightly in their points of origin from those in the rabbit, the formation of this vessel in the rabbit does not contribute to the formation of a fourth vessel arising from the arch of the aorta, as is the case in man, but does form a fourth vessel from the innominate. In a single case, as shown in figure 11, the arch of the aorta gives rise to but one vessel, an innominate, which passes cephalad for some distance before it breaks to form, first, the left subclavian, and a little further forward the left common carotid artery, and the brachiocephalic artery. This peculiar variation is interesting, since it closely simulates the normal condition found in the horse. It may be explained by the fusion of the two aortic stems and the shortening of the fourth arch so that the left subclavian artery joins with the common stem during the transformation of the primary vessels. In one instance the left vertebral (fig. 3, V) takes its origin well

down on the left subclavian vessel so that it is almost in a position to be considered a separate branch from the arch of the aorta and could be interpreted as an additional vessel from the latter as has been recorded as a variation in the human (McMurrich, p. 511). It is easy to see how by a slight displacement caudad of the left common carotid artery in this case would produce four distinct vessels originating from the arch of the aorta instead of the usual two.

SUMMARY

Although the usual number of blood-vessels arising from the arch of the aorta in the rabbit is two — a so-called innominate or brachiocephalic artery and a left subclavian artery—the variations from this condition herein described indicate the possibility of a considerable departure. In one individual (fig. 11) a single vessel leaves the aortic arch, and after passing a short distance forward subdivides successively to form the left subclavian, the left common carotid, and the innominate or brachiocephalic arteries, the latter subdividing again to form the right common carotid and the right subclavian arteries.

In a number of cases, as shown in figures 6, 8 and 10, three vessels have their origin on the arch, and in these the order is the brachiocephalic, the left common carotid, and the left subclavian arteries. In one individual (fig. 3) the left vertebral replaces the left common carotid artery in the series, the carotid in this case having its orgin on the innominate as normally. This case suggests the possibility of four vessels forming the series.

Conspicuous differences in the order and sequence of the vessels from the subclavian arteries of the two sides are noted. On the left side the vessels in a number of cases show a tendency to group themselves either proximally or distally in the form of a short corona, as indicated in figures 6, 9 and 10. The formation of various innominate stalks common to certain arteries are found in some cases, while in others the intervals between certain arteries are rather noticeable. Less marked variations are noted in the vessels of the right side. The vertebral artery in

one instance (fig. 2) is displaced from its usual place to the lateral side of the right common carotid artery. The transverse scapular artery in two cases is a branch of the vertebral, while the superficial cervical, which is normally a branch of the transverse scapular, in one case (fig. 10) leaves the subclavian as a common stalk with the intercostal and mammary arteries.

In three cases a small so-called thyreoid ima is present, and in these this passes forward from its origin between the two common carotids, thus having the same morphological position in the rabbits as a similarly described vessel occupies in the human.

PLATE 1

EXPLANATION OF FIGURES

1 Diagrammatic ventral view of the arteries of the thoracic region of the rabbit, showing the various branches as they occur in the majority of specimens. The innominate (brachiocephalic) (*N*) and the left subclavian (*S*) are the two usual branches of the arch of the aorta. The left subclavian gives origin to a number of arteries as here shown, while the innominate bifurcates to form the two common carotids and the right subclavian arteries.

2 Schematic ventral view of the arteries of rabbit 32, which conspicuously indicates the vertebral artery of the right side as a branch of the right carotid artery. Notice on the left side the transverse scapular and the vertebral arteries are morphologically interposed and the intercostal and mammary arteries are separated by quite an interval. The left common carotid is well down at the base of the innominate, almost constituting a separate branch of the arch of the aorta.

3 Ventral view of the arteries in rabbit 40. The vertebral artery of the left side is here formed close to the junction of the subclavian with the aortic arch, and thus forms what may be considered a third branch of the arch. The intercostal and mammary arteries of the left side are separated by a wide interval.

4 Rabbit 53 shows the formation of common stalks (innominates) for the intercostal and mammary arteries of both sides as well as the transverse and superficial cervical of the right. The brachiocephalic gives rise immediately to the left common carotid.

5 The arteries of rabbit 22 show differences in branches of the right and left subclavian vessels especially. The intercostal and mammary arteries originate separately on the right, the vertebral on the left is well cephalad of the other vessels, and makes a bend caudomesad as here shown. Accessory vessels are found on the left side also.

6 In rabbit 28 the formation of what may be termed a long corona of the left subclavian with a migration of the intercostal from the lateral surface of the subclavian to form a common stalk with the vertebral artery. The left common carotid artery is here a branch of the aortic arch so that three distinct branches are formed. The innominate is conspicuously long.

7 Specimen 19 shows among other variations the formation of the thyreoid ima, a small vessel originating on the innominate just caudad to the point of origin of the left common carotid artery and passing forward to the thyreoid gland of the neck.

8 Rabbit 21 shows interesting relationships of the innominate, left common carotid, and left subclavian arteries, and shows the comparatively immediate subdivision of the subclavian of either side. Such a condition may be designated as the short corona type.

9 Specimen 106 shows the so-called thyreoid ima and other minor variations especially in the interval between the intercostal and mammary arteries of the right side, and the formation of the short corona type of the left subclavian artery.

10 In rabbit 85, beside the thyreoid ima being present, the left subclavian takes its origin on the arch and the superficial cervical of the right side passes out from the common stalk of the intercostomammary artery. The subclavian of the left side forms a short corona.

11 In rabbit 52 the innominate (brachiocephalic) artery is the only vessel originating on the arch of the aorta, and subsequently subdivides as shown, giving rise to a long corona typed left subclavian, left and right carotid arteries, and right subclavian artery. This condition thus typifies that found normally in the horse.

A suggestion for improvement in projection and drawing apparatus.

By substituting a focusing stage in the drawing apparatus, provided with coarse and fine adjustments, in place of the fixed stage used at present, variations in the magnification of the projected image due to focusing are eliminated, hence more accurate results in reconstruction work may be expected, even when slides and cover-glasses in a given series are not of uniform thickness. The customary arc lamp is discarded for a new commercial form of incandescent illuminant which greatly facilitates the control of the light.

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED
BY THE BIBLIOGRAPHIC SERVICE, JUNE 21

A SUGGESTION FOR IMPROVEMENT IN PROJECTION AND DRAWING APPARATUSES

JOSEPH M. THURINGER

Department of Anatomy, Tulane University of Louisiana, New Orleans, Louisiana

ONE FIGURE

Among the various types of apparatus manufactured for the projection of microscopic objects for tracings and drawings, the Edinger drawing and projection apparatus no doubt holds first place, both from a point of usefulness and of mechanical stability. For the drawing of individual microscopic objects it leaves little to be desired, except perhaps an improved form of illuminant. However, when used for the drawing of serial sections for reconstruction work by any of the various methods in vogue, we are at once confronted with a little more difficult problem.

It is highly desirable to hold the percentage of error in reconstruction work to a minimum. A well-prepared series of sections, of course, is the essential factor. Secondly, this series should be mounted with slides and cover-glasses of uniform thickness. Even the mounting medium should be of uniform consistency and temperature for a given series, and all the slides after mounting subjected to a drying for a given number of hours at uniform temperature to insure an absolutely equal distribution of the mounting medium over the entire surface. With all these precautions carefully observed, there still remains an appreciable source of error due to the difference of magnification obtained when using the present focusing devices. The slightest change in position of the draw-tube alters the magnification. To increase the efficiency of the above-mentioned apparatus the following changes are suggested and illustrated in the accompanying drawing.

The stage as manufactured at present is only equipped with a clamp (K) for altering its position. This, however, does not

permit sufficiently convenient and accurate adjustment to answer the purpose of a focusing stage. The most painstaking care in the determination of the magnification by means of stage micrometer and rule will be upset by the slightest change in position of the draw-tube or by having to refocus. To obviate this source of error the focusing stage illustrated (*S*) is suggested It is equipped with a coarse and fine adjustment identical with the one supporting the draw-tube of the microscope (*M*) and therefore not entailing great additional cost in the manufacture. This stage could also be supplied to all Edinger apparatuses in present use, thereby bringing them to their highest efficiency. After the desired magnification is once determined, all future adjustments are made by means of the stage coarse and fine adjustments. All errors due to differences in thickness of slides, cover-glasses, and mounting media are thus compensated.

The condenser (*C'''*) is hinged on a support and guided by an upright which, however, is not secured to the stage, as at present, thus permitting more room for the use of a mechanical stage.

The arc lamp, which always required more or less attention and needed new carbons at the most inopportune moment, is here replaced with the new low-voltage, high-amperage, concentrated-filament, incandescent lamp. On direct current this is operated in series with a suitable resistance and on alternating current with a small transformer. Both of these devices can be attached under the drawing table and require no further attention when once adjusted.

The lamp is held by a universal support (*U*), which allows adjustment vertically as well as horizontally, thus permitting the use of various-sized lamps.

A light-tight, ventilated hood, provided with an adjustable reflector (*R*), completes the outfit.

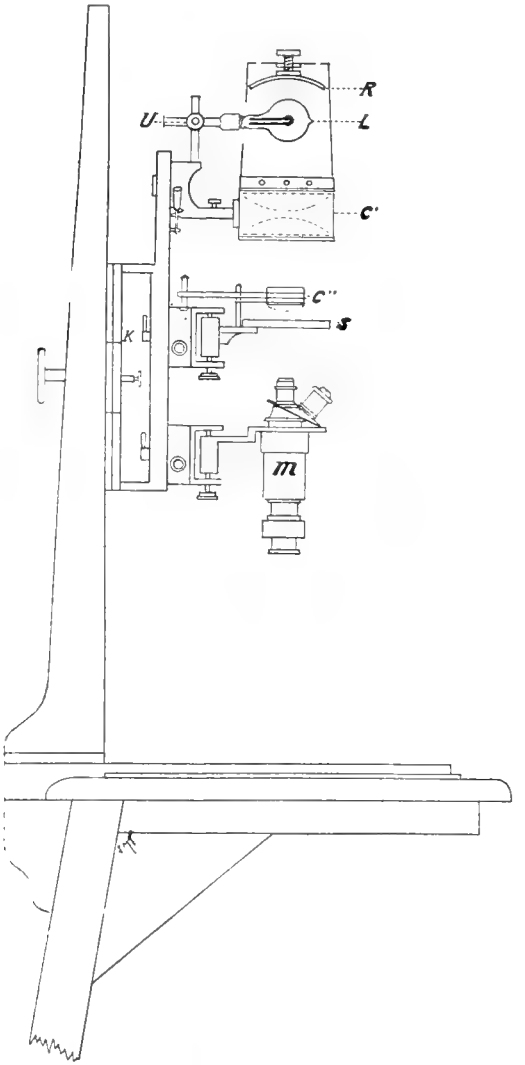

Fig. 1. Diagram of projection and drawing apparatus. *C''*, stage condenser; *C'*, condenser; *L*, lamp in ventilated housing; *R*, adjustable reflector; *U*, universal support; *S*, focusing stage; *K*, clamp; *M*, microscope.

Symmetrical bilateral dystopia of the kidneys in a human subject, with outward rotation of the hilus, multiple arteries and veins, and a persistent posterior cardinal vein.

In a male human subject, aged twenty-eight, who died of pulmonary tuberculosis, an associated series of rare anomalies of the kidneys was found. There was a symmetrical bilateral displacement caudally, each kidney lying from the level of the second to the fifth lumbar vertebrae. Symmetrical displacement without fusion is rare. The hilus forms a long, narrow groove, the upper part lying on the anterior surface of the kidney, the remainder describing a spiral cutting around the outer border on to the posterior surface as it proceeds caudad. This lateral position of the hilus is extremely rare, previous ones being found in pelvic kidneys, and very few instances being recorded. On the right side were five renal arteries, two off the aorta, three from the common iliac artery. There were four left renal arteries, two from the aorta, one from the common iliac, and one from the hypogastric arteries. Two spermatic arteries were present on the right side and three on the left. Two renal veins, uniting into a short common stem tributary to the inferior vena cava, occur near the upper pole of each kidney. In addition, on the left is a posterior cardinal vein connected at the ends to the common iliac and upper renal veins and having as tributaries a third renal vein and four lumbar veins. A fourth left renal vein goes to the hypogastric vein. The pelvis of the ureter enters the kidneys anterior to the main vessels. The ureter courses lateral to the kidney.

SYMMETRICAL BILATERAL DYSTOPIA OF THE KIDNEYS, IN A HUMAN SUBJECT, WITH OUTWARD ROTATION OF THE HILUS, MULTIPLE ARTERIES AND VEINS, AND A PERSISTENT POSTERIOR CARDINAL VEIN

JAMES CRAWFORD WATT

Department of Anatomy, University of Toronto

TWO FIGURES

In the laboratory of the Department of Anatomy of the University of Toronto a very interesting series of associated anomalies relating to the kidneys and their vessels was discovered during the regular course of dissection. The specimen was at once put aside for investigation, and on further study has been considered worthy of a detailed description.

The body was that of a well-proportioned but somewhat emaciated male, aged twenty-seven, who died of pulmonary tuberculosis. Apart from the abnormalities associated with the kidneys, no other gross anomalies were noticed in this subject.

THE KIDNEYS

Shape and size (fig. 2)

The outline of the kidneys is that of a long, narrow oval. The ventral surface is quite convex, the dorsal surface flattened. Of the two poles, the lower is much thicker than the upper. A shallow groove winding spirally from the ventral surface laterally and caudally on to the dorsal surface forms the hilus, and notches the outer border where it crosses it. Except for the presence of the hilus, the surface is smooth, and shows no special lobulation.

The measurements taken are as follows:

	Right kidney	Left kidney
Greatest length	10.5 cm.	11 cm.
Width	3.5–4.5 cm.	3.5–4.5 cm.
Thickness	2.5–3.5 cm.	2.5–3.0 cm.

Position and relations (fig. 2)

The two kidneys exhibit a displacement which is quite symmetrical on both sides. Each lies close in against the psoas

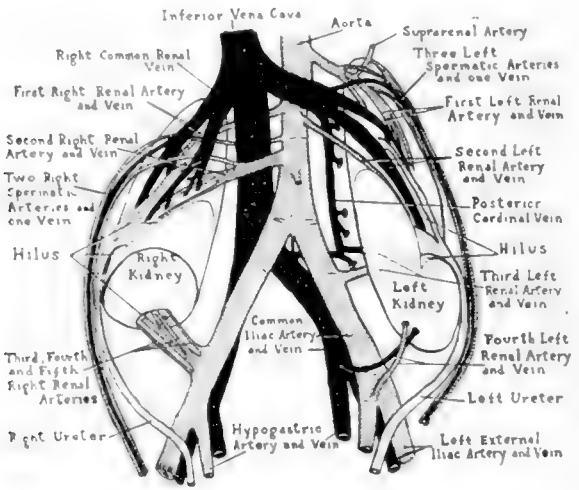

Fig. 1 Outline drawing of the kidneys and their vessels and ureters. Veins are solid black, arteries striped, and ureters stippled. Lower part of right kidney removed.

major muscle and shows the same degree of obliquity as the muscle. The upper pole of each kidney is about 1 cm. nearer the midline than the lower pole. The upper pole is opposite the middle of the second lumbar vertebra, the lower oposite the lower part of the fifth lumbar. The kidney thus lies with its upper portion in the lumbar region, on the quadratus lumborum muscle, the other portion in the iliac fossa, on the iliacus muscle.

The suprarenal glands were placed over the upper pole and slightly to the medial side of each kidney. The left gland was

situated in a small space with the kidney below, pancreas above, spleen laterally and vertebrae medially.

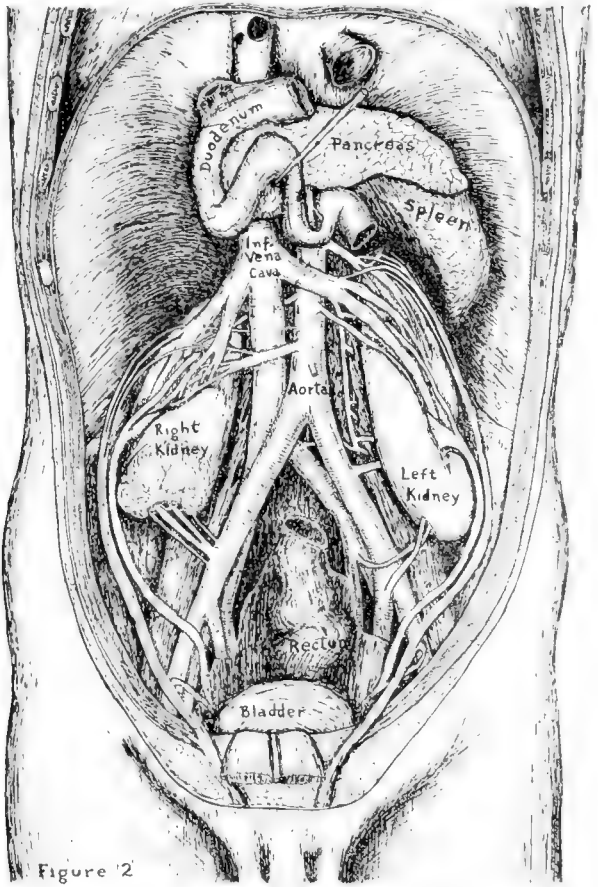

Fig. 2 Drawing of the kidneys to show their relations to the dorsal abdominal wall and the viscera. The duodenum, pancreas, and spleen have been retained in position, the lower part of the duodenum being hooked up to expose the underlying vessels. The suprarenal glands have been removed to expose the upper pole of the kidney. Lower part of right kidney removed.

The pancreas was situated entirely above the left kidney and crossed right over the spleen. Owing to the downward displacement of the kidney, the spleen was displaced inward and

was in contact with the vertebrae medially for two-thirds of its length. The lower pole, however, had the upper pole of the kidney inserted between it and the vertebral column.

On the right side the kidney and suprarenal gland lay entirely below the level of the liver, which was thus allowed to come into contact with the diaphragm on its posterior surface.

The upper pole of each kidney and the common renal vein from each side were under cover of the duodenum at the flexure of the latter at the lower end of the descending limb.

The hilus (fig. 2)

The position of the hilus is most interesting, and is quite similar on both sides. Starting above, about three centimeters below the upper pole, on the anterior surface, it runs obliquely caudad to cut the lateral border of the kidney, forming a notch on it about two thirds of the way down. It then curves from here on to the posterior surface, ending about two or three centimeters from the lower end of the kidney.

The hilus is thus placed on the opposite border to the normal and forms a spiral with gradually increasing rotation about the polar axis as it proceeds caudad.

VESSELS

Arteries (figs. 1 and 2)

The renal arteries and also the spermatic arteries of both right left sides are multiple.

Right side. The right renal arteries are five in number. The first comes off the abdominal aorta at the level of the second lumbar vertebra and goes behind the inferior vena cava to the upper end of the hilus on the anterior surface of the kidney. The second renal artery also goes to this surface, coming from the aorta at the level of the third lumbar vertebra and running in front of the vena cava.

Off the right common iliac artery come the third renal artery, a very small one, the fourth, quite large and dividing early into

two, and the fifth, a small artery again. These three arteries running in close company pass behind the lower pole of the kidney and enter the lowermost part of the hilus on the posterior surface.

The right spermatic arteries are two in number. The higher one arises from the aorta between the first and second renals, and runs posterior to the inferior vena cava and both renal veins, but anterior to the upper pole of the kidney. The lower artery arises from the second renal, goes posterior to the inner renal vein, anterior to the outer vein, and anterior to the kidney. At the lateral border of the kidney the two spermatic arteries and the vein form a common bundle running in contact with this border and the ureter in the iliac fossa, and then turning over the psoas muscle to the internal abdominal ring.

Left side. There are four left renal arteries. The first is off the aorta at the upper limit of the second lumbar vertebra and runs down anterior to the upper pole of the kidney. The second artery is from the aorta, over the second lumbar vertebra, level with the highest artery on the right. It is also to the hilus on the upper part of the anterior surface of the kidney.

The third left renal artery is off the left common iliac, and is peculiar in that it runs across the upper part of the iliac fossa behind the kidney, to pass into the hilus just where it cuts across the lateral border.

The fourth artery is off the internal iliac, or hypogastric artery, just at its commencement, and runs anterior to the external iliac artery and psoas major muscle and penetrates the kidney on its medial border just near the lower pole.

On this side there are three spermatic arteries, the highest coming off a suprarenal branch of the first renal, the other two directly off the first renal. All three arteries and the spermatic vein form a common bundle coursing anteriorly along the lateral border of the kidney, then lateral to the ureter in the iliac fossa and down to the inguinal canal.

Veins (figs. 1 and 2)

Right side. There are two renal veins, both coming from the upper part of the hilus over the anterior surface of the kidney, and uniting at the level of the upper pole of the organ into a common vein which is about three-quarters of an inch in length and empties directly into the inferior vena cava.

The right spermatic vein, a single vessel, opened into the lateral of the two renal veins.

Left side. On this side are three renal veins. Two are quite similar to those on the right, arising from the anterior surface of the kidney on the upper part of the hilus and uniting into a common stem which crosses anterior to the aorta and empties into the inferior vena cava.

Just at the junction of the above two veins, there comes into the medial one, a longitudinal vein which lies over the front edge of the psoas muscle, on the vertebral column, in the interval between the aorta and the left kidney. This stem starts at the level of the fifth lumbar vertebra, and communicates with the left common iliac vein below. As it ascends it receives as tributaries four lumbar veins, one of which is double, and also a renal vein. This renal vein comes from the hilus where the latter cuts the outer border of the kidney, and runs medially posterior to the kidney, alongside of the third renal artery, and ends in this ascending vein. This longitudinal stem is interpreted as a persisting portion of the embryonic posterior cardinal vein of the left side, which lies exactly in the position occupied by this present vein.

The left spermatic vein, single in spite of the presence of three arteries, empties at the junction point of the two large upper renal veins into the common trunk.

Ureter (figs. 1 and 2)

The position and relations of the ureter are remarkably symmetrical on the two sides.

At its pelvis, each ureter is divided into two parts. One is a long, narrow, tubular portion which lies in the upper part of

the hilus, on the anterior surface of the kidney. The other is a broad, short, funnel-shaped portion communicating with the kidney in the hilus just before the latter cuts round the outer border of the organ.

The two parts unite at the lateral border of the kidney, which the ureter now follows to the lower pole, where it then crosses the iliac fossa, turns medially over the psoas muscle and external iliac artery into the pelvis, where its course into the bladder is normal.

The highest artery and the lateral vein accompany the upper branch of the ureter as it enters the kidney, the vessels lying behind. The other vessels enter the kidney mostly behind the lower branch of the ureter.

SIMILAR CASES

Multiple renal arteries and veins in all the locations found in this case have been previously described and discussed by various authors, and so call for no special consideration. Tonkoff ('03), for instance, describes and gives a figure of a right kidney slightly displaced downward and with an arrangment of its four renal arteries almost identical with those of the left kidney in this case.

Macalister ('83) and Morris ('85) both state that abnormal vessels occur in three individuals out of every seven.

The occurrence of a vena cardinalis posterior along with renal anomalies has been noted before. Melissinos ('11) found a case of pelvic kidney with a persistent right cardinal vein, and gives reference to a few other instances.

The presence of the rotation seen in these kidneys, on the contrary, is evidently quite a rare condition. Among the anomalies of position of the hilus, the particular one exhibited here is not even mentioned in the text-books on pathology or surgery. It is self-evident that such a position would be of great interest, especially to the surgeon.

Gerard ('05), in a review of 527 cases, states that the renal hilus, instead of lying medially, may be superior, inferior, ventral, or dorsal, but does not mention any instance of a lateral position.

Müllerheim ('02) describes a case where the left kidney was found in the pelvis, with its hilus not medial, but anterior, and he states that one of the characteristics of dystopia of the kidney is that the hilus is usually anterior in position.

Morris ('04), in a summary of displacements, states that the kidney may be rotated so that the hilus looks upward, outward, directly forward or backward, and mentions one case of the hilus occurring laterally. This case was described by Farquharson ('94) as a left kidney placed in the pelvis with hilus looking to the left.

Brown ('94) also describes a right pelvic kidney which had rotated till its posterior surface had become anterior and the hilus looked posteriorly to the right. Johnson ('14) described a case in the cat exactly similar to that of Brown's and Anitschkow ('12) describes and gives a figure of a left kidney in man displaced slightly back in the lumbar region and with a hilus which he describes as anterior, but which, in the illustration, appears to course around the lateral border, as there is a marked indentation shown there.

McMurrich ('98), considering a series of crossed dystopia of the kidneys with fusion, pointed out that in nearly all cases the position of the hilus was anterior.

This retention of an anterior position of the hilus in displacements and in fusions of the kidneys is the retention of the normal embryological position. Pohlman ('05) noted that until the kidney had ascended in the embryo to where it was approximately in the adult position, the hilus was ventral, and then a rotation medially of 90° occurred about the polar axis. Felix ('12) also states that this rotation occurs, but that a reverse rotation toward the ventral surface also occurs later, so that the hilus is finally ventromedial.

The kidneys in the present case have not reached the usual final level and so might be expected to have retained the hilus anteriorly. This is true of the upper part, but the lower portion exhibits the rare outward rotation through 90° to bring it laterally, and the lowest part goes even further than this to lie posteriorly. There is thus considerable torsion in the kidney, the hilus forming quite a spiral in its course.

The fact that the ureter lies ventral to the main renal vessels at the hilus at first sight appears as an anomaly. It will be seen, however, that if the hilus were to be rotated into its usual position the ureter would then lie posterior to the vessels. Thus at their entrance into the kidney these structures stand in their normal relations to each other, but the rotation makes them appear reversed.

The position of the suprarenal glands is interesting. McMurrich, Morris, Müllerheim, and others have all stated that the relation of these glands to the kidneys is merely topographical and that they are found in their usual places in cases where the kidneys are displaced. In this instance, however, they lie closely capping the upper pole of each kidney, and so are displaced somewhat caudally from their normal location.

What was the actual cause of all the anomalies shown above is open to conjecture. It must have been a force acting in early embryonic life. The displacement into the iliac fossa was probably due to lack of growth in the ureter and the torsion due to a twisting of the pelvis of the ureter. It is of interest to note that Felix ('12) states that in the lumbar region the ureter shows a dilatation accompanied by a spiral twisting. An exaggeration of this process might possibly account for the result shown here. Whatever the cause may have been, the result is most remarkable for instead of a symmetrical displacement of the whole organ, we have here the upper pole with the upper end of the hilus facing still in the old embryological position, while proceeding caudad there is an ever-increasing torsion evident, until finally at the lower end the hilus shows a displacement of 180° brought about by lateral rotation.

The position of the kidneys in the lower lumbar region and iliac fossa seems to be a much rarer condition than the position within the pelvis, as by far the greatest majority of cases of dystopia without fusion are reported as being in the pelvis.

The symmetrical degree of dystopia shown by these two kidneys seems to be almost as rare a condition as the lateral hilus. In all the cases quoted above and in many others not mentioned here, if the two kidneys are not fused to form the discoidal or the

horseshoe kidney, either there is a much greater degree of dystopia on one side than on the other or else only one kidney shows displacement, the other being in its normal position. Thus the kidneys in this instance are unique in several respects and have therefore seemed well worthy of description.

THE ANATOMICAL RECORD, VOL. 19, NO. 4
SEPTEMBER, 1920

Resumen por el autor, Eben James Carey.
Colegio Médico Creighton, Omaha.

Estudios sobre la dinámica de la histogénesis. La fuerza que motiva el crecimiento como estimulo dinámico en la genésis de los tejidos esquelético y muscular.

La región activa dominante en el crecimiento del intestino es el tubo epitelial; la zona que crece menos activamente es el mesenquima que le rodea. En el colon terminal del cerdo el tubo epitelial crece en dirección caudo-cefálica. Las figuras mitósicas siguen en su mayor parte la dirección de una hélice sinistrorsa. En embriones de cerdo de 10 a 25 mm. de longitud, el colon terminal crece relativamente con mas rapidez en diámetro que en longitud. Durante este periodo la túnica interna de músculo liso está en periodo de formación. Cuando el embrión crece desde los 25 a los 45 mm. el colon terminal crece mas rápidamente en longitud que en anchura. Durante este periodo de alargamiento intestinal rápido se inicia la capa externa de músculo liso. La correlación del crecimiento tubular epitelial en longitud y anchura, con la génesis de las túnicas musculares lisas interna y externa, respectivamente, se considera bajo el aspecto de "fuerza que motiva el crecimiento." La región de crecimiento acelerado en el miembro en vías de desarrollo es el núcleo esquelético central; la de crecimiento retardado es el mesenquima que le rodea, el cual se transforma ulteriormente en la musculatura y tejidos conectivos relacionados con ella. Estas dos zonas de crecimiento diferencial se influyen mutuamente, y esto es evidente objetivamente a causa de un cambio de movimiento y por una alteración de la forma externa y estructura interna de las células afectadas. El primer material óseo del embrión se distribuye económicamente en la periferia al principio, sobre la superficie convexa mas débil del fémur curvo. Después el hueso envuelve al centro de la diáfisis y aparece en el lado cóncavo del fémur cartilaginoso curvo. La correlación entre el crecimiento esquelético acelerado y el desarrollo mesenquimático retardado se considera con referencia a la "fuerza que motiva el crecimiento diferencial."

INTRODUCTION

The principle of unequal growth constantly confronts the embryologist in his investigations. The local thickenings and foldings of the central nervous system, the unequal growth of the cardiac septa, the elongated intestinal tract, are common instances exemplifying the principle that the body parts develop at different rates.

This idea was recognized by Aristotle, but was not definitely formulated until 1774 from Wolff's convincing studies. In the latter's work on intestinal development the principle of unequal growth was definitely established and elaborated considerably. In 1874, His compared the various layers of the chick embryo to plates and tubes of an elastic nature. From these he suggested that some of the principal organs are molded by local zones of unequal growth. Davenport ('96) resolves the changes in ques-

tion into movements of cells or cell aggregates, the latter being linear, superficial, or massive. He still further classifies each of these three divisions.

These local zones of unequal growth and the movements of cells have been looked upon by Herbst ('94) and Dreisch ('94) as physiological responses to definite stimuli. His and Davenport as well as Roux ('95) aim at something more than a mere description of unequal growth and ontogenetic events. They made an attempt to give a mechanical causal explanation for these processes. The function and aetiology were considered side by side with structure.

It is from the dynamic view-point that the present investigation was pursued. It is desired to emphasize the fact that in zones of unequal or differential growth, in limb and intestinal development, that an interaction of forces takes place, resulting in a transference of energy, and that these forces are factors in histogenesis. This action and reaction and transference of energy is due to a definite entity, growth motive force, a term introduced by the writer.

Growth motive force is any agency which tends to produce a transfer of kinetic energy, from an active to a less active group of cells, and of potential energy from a less active to an active group, in a cellular field of differential growth until equilibrium is established. The active and less active zones are in reference to the rate of cell division per millimeter of cross-section. This principle was deduced from a series of studies on osteogenesis and myogenesis begun in 1914. Previous reports of a part of this work have been presented to the Association of American Anatomists (Carey, '17, '18, '19).

The understanding of the causes underlying tissue formation or differentiation of an unspecialized cell is the central difficulty for the student of development.

The increase of cellular components, the transformation of these, and the perfection of form out of the relatively formless antecedents are phenomena which demand the closest analysis. Growth and division of the nucleus, however, are merely changes concomitant with the specialization which the cell undergoes.

There are three theories regarding cellular differentiation: first, the 'mosaic theory' of Roux ('88), later modified by Wilson ('04), Conklin ('05), Zeleny ('04), and Boveri ('04); second, the 'organization theory' of Whitman ('93) and more recently elaborated by Child ('15) in the latter's studies on metabolic gradients and individuality; third, the 'homogeneity theory' of Dreisch ('91–'93). Dreisch considers the peculiar organizing quality of protoplasm as due to the expression of a mysterious force wholly different from any in the inorganic world.

At least in certain of the earliest stages, the primordial cell is modified during development by the environment. It is not independent in its development but is dependent upon an interaction of developing parts before its external form and internal structure are perfected. This is the theory expressed by the terms, mutual interaction, correlation, interdependents, dependent differentiation or differentiation due to position. This theory is upheld by His ('74), Hertwig ('94), Fischel ('98), Von Baer (1828), Pfluger ('83), C. Schultze (1900), Hans Dreisch ('94), Zoja ('95), Whitman ('94), Child ('99) and Thoma ('07) and to a limited extent by Roux. The latter investigator distinguished two periods in the development of the body parts: first, a period of self-differentiation in which the parts arise, grow, and differentiate of themselves; second, a period of functional form development in which the more complete formation of the parts is accomplished through the influence of stimuli.

As to the first view, it has been convincingly proved that there are organ-forming stuffs in the cytoplasm. Wilson ('04) concluded from his studies that the cytoplasm of the primordial germ cell contains certain specific organ-forming stuffs which have a definite arrangement. These observations of Wilson have been confirmed by Conklin ('05), Zeleny ('04), Boveri ('04).

The third theory regards differentiation as dependent upon either an extrinsic or an intrinsic factor. Differentiation so considered is in the nature of a physiological response to a stimulus. The structure of the reacting as well as of the stimulating body, however, contributes to the quality of the effect. Specialization by this method is simply an 'induction,' according to Dreisch.

It is an effect produced upon the parts that are developing by other developing parts or by an extrinsic factor in the environment. Three elements are consequently involved: first, the stimulus; second, the reception of the stimulus; third, the response. The first is some other organ or external agent; the second and third are functions of the organ in process of formation. Lack of evidence has been the chief obstacles to the acceptance of Dreish's theory of induction.

The term 'induction' implies an effect or change produced without contact. But, in respect to the primordium of the muscular and skeletal tissues, there is a definite syncytial continuity. Consequently, any effect produced by either tissue upon the other would be through 'conduction' and not through 'induction.'

In this action, through conduction of the developing skeletal and muscular tissues upon each other, the factor of force is inherently involved. The primordial blastemal skeleton is undergoing the most rapid growth, as a consequence of which a tensional elongating or stretching action is bound to be exerted upon the surrounding and less actively growing, continuous, syncytial mesenchyme. It is desired, therefore, to emphasize the following facts:

First, that there is a force manifested by rapid skeletal growth.

Second, that this force exerts a tensional or stretching action upon the surrounding mesenchyme, influencing the first steps of myogenesis.

Third, that the first differentiated muscles react upon the primordial blastemal skeleton resulting in a definite series of changes. These are seen in the formation of the condensed cartilaginous skeleton and later, as the muscles become more developed and vigorous in physiological function, in the formation of the osseous skeleton.

This action and reaction of forming parts results in the condition that at any period of development the degree of differentiation of the musculature and skeleton represents an equilibrium established between opposing myogenic and skeletal forces. Mechanically, therefore, skeletal and the related muscular tis-

sues are interdependent, one relying upon the other for its initial and continued differentiation.

The foregoing applies to the skeleton and skeletal cross-striated musculature. Concerning the smooth muscle of the intestine there is a similar interaction of differential forming parts. The epithelial lining of the alimentary tube is the most active region of growth. The growth in diameter in the early stages is due almost entirely to the rapid degree of mitosis of the epithelium and not to the surrounding mesenchyma forming the bulk of the wall. As a consequence the lumen rapidly increases in diameter, and it is this increase which causes primarily the diametrical growth of the intestine. It is readily apparent that the rapid distention of the lumen due to epithelial growth would cause a tension upon the relatively passive, contiguous, syncytial mesenchyme. This action would tend to draw out or stretch the mesenchymal cells in a concentric manner somewhat similar to the tension put upon the strained elastic fibers of a rubber balloon when distended with air, the pressure of epithelial growth being comparable to the air pressure.

Once the encircling mesenchymal cells have formed a definite ring, the expanding lumen would meet a resistance to growth in diameter. The growth force, pursuing the lines of least resistance, would be directed in a longitudinal manner due to the shifting of the planes of mitosis from a longitudinal to a transverse direction. This shift is directly due to the external resistance of the first-formed ring of inner circular smooth muscle.

At this point the term force is one that will stand close scrutiny and careful thought on the part of the embryologist. A force is one of a pair of equal, opposite, and simultaneous actions between two bodies by which the state of their motions is altered or a change in form in the bodies themselves is effected. Pressure, attraction, repulsion, and traction are instances in point. Muscular sensation conveys an idea of force, while a spring balance gives an absolute measure of it, and a beam balance only a relative measure. In accordance with Newton's third law of motion that action and reaction are equal, opposite, and simultaneous, forces always occur in pairs.

Force is exerted in certain regions of the embryo by the genesis of a rapidly dividing group of cells upon a less active or relatively passive group of cells. In turn the relatively passive group react upon the former. This action and reaction is objectively evident by a retardation or alteration of the rate of growth or by a change produced in the external form or internal structure of the cells involved.

The most rapidly dividing group of cells in a differential growing cellular field in syncytial continuity is subjected to a force tending to direct it in the path in which the resistance diminishes most rapidly, that is in the direction of a line of force. The most rapidly growing cells raise the kinetic energy of the field at the point of rapid growth above that of surrounding points, and hence a transference of energy takes place until equilibrium is established. There will be a transfer of kinetic energy from the growing to the passive group of cells resulting in an elongation of the latter and a consequent storage of potential energy due to position. On the other hand, there will be a transference of potential energy from the elongated relatively passive group of cells to the moving or growing group which will tend to restrict or retard the motion or growth of the former. This motive force of genesis, growth, and differentiation continues until the difference in energy disappears.

These biological generalizations are analogous to electromotive force. If two metal spheres at different potentials be connected by a wire, a transfer of positive electrification will take place from the one of higher to the one of the lower potential, or a transfer of negative electrification from the one of lower to the one of higher potential, or of both, until the difference of potential disappears. The higher and lower electrical potentials are analogous to the continuous zones of rapidly dividing and less active group of cells, respectively. The term electromotive force is applied to any agency which tends to produce a transfer of electrification as exemplified above. Growth motive force consequently may be defined as any agency which tends to produce a transfer of kinetic and potential energy in a cellular field of differential growth.

EARLY STAGES IN THE HISTOGENESIS AND MORPHOGENESIS OF THE DESCENDING COLON OF THE PIG (SUS SCROFA)

The increase or decrease in size of certain parts of the intestine and the cellular transformations which occur are of fundamental importance. By analysis and careful description of the changes which occur in sequence and by subsequent synthesis of the data obtained, an interesting correlation in dynamics is thereby detected. Heretofore investigators of histogenesis have had independent and isolated view-points in their work on intestinal development, no correlation of the developmental processes being attempted. The admirable descriptive observations on intestinal development by McGill ('07) and Johnson ('11) fulfill the purpose of their respective authors, but lacked interpretation and correlation of the facts observed. Their point of view was descriptive morphology, not dynamic.

In an embryo 10 mm. in length the descending colon presents in cross-section an oblong oval or pear-shaped appearance, the convexity of which is directed toward the interior of the abdominal coelomic cavity. The tapering end is attached to the dorsal abdominal wall through the intermediation of the relatively long and thick dorsal mesentery. There are three main elements which demand close attention (fig. 1). The first of these is the inner epithelial tube; the second, the outer peritoneal epithelium, and the third, the intermediate mesenchymal zone.

The inner epithelial tube in cross-section is oval in shape containing a narrow oblong lumen with rounded ends. The lining cells of this tube form from two to three rows of nuclei. Mitosis is usually found in the superficial row of cells. At this stage mitotic activity is prominent in the epithelial cells. The basal row of cells rest upon a well-marked basement membrane.

This basement membrane is directly contiguous to the intermediate mesenchymal zone. In this zone no clear-cut cell is found. The entire region is composed of protoplasm in syncytial continuity, embedded in which are found the nuclei. The nuclei are oval or round and present a very dense network of chromatin, especially well seen when stained with iron-hematoxylin. The membranes of the nuclei are decidedly distinct. The protoplasm

is granular, presenting an irregular network structure. Scattered in the mesenchymal region are seen isolated discrete vesicles. These are especially congregated toward the dorsal mesenteric attachment. The vascular vesicles are variable in size and shape and present various degrees of confluence.

The thickness of the mesenchymal wall is nearly twice that of the diameter of the epithelial tube. It is to the rapid increase in diameter of the latter, due to rapid epithelial mitosis, that the increase in width of the intestine is to be ascribed. The mesenchyme remains relatively passive, and as a consequence is put under great tension by the internal distention of the epithelial tube.

Attention is especially directed to this difference in the rate of growth between the inner epithelial lining and the intermediate zone of mesenchymal cells. The continued differentiation of the intestine is pivoted upon this fact. Furthermore, the epithelial distention is not a uniform one. Mitosis takes place in a spiral manner from the anal toward the ileocecal valve. Consequently, the rapid growth of the epithelial tube is a specific type from below upwards.

The attention of the writer was directed to the fact, after plotting hundreds of intestinal epithelial mitotic figures, that these figures were usually confined to some definite region of the circumference of a single section. This region was found to change at different levels of the serial sections. By graphic reconstruction (sections 45 to 94) this plot was found to form the path of a definite spiral describing a dexiotropic rotation in one case; in nineteen others the path was a left-handed spiral. The spiral itself presented a head or apical region in which mitotic figures were found to be numerous and a tail or basal end in which there were fewer and fewer figures. The apical end of the spiral path is always directed toward the iliocecal valve and the basal end toward the rectum. Growth is therefore from below upward in a spiral course. One spiral growth is quickly followed by a second which rifles a path slightly lateral to its predecessor. This in turn is followed by a third, in a path still more lateral, and so on around the circumference. This intermittent rhythm

of explosive spiral growth may be compared to that of the successive fire balls emitted by a roman candle in fireworks. The paths formed by this explosive spiral growth may be compared to those within the barrel of a Winchester rifle.

Lining the outer peripheral portion of the mesenchyme is the peritoneal epithelium. In the 10-mm. embryo this is a single layer of oval or cuboidal cells. These are continuous from the dorsal mesentery and envelop the primitive colon proper. The cell walls of this layer are contiguous and give a beaded appearance to the peritoneal epithelium. Later in development this cellular layer becomes flattened and markedly elongated, the individual cells becoming more and more attenuated and spindle-shaped.

The beginning of this flattening or elongation of the peritoneal epithelium is seen in a 14-mm. embryo (fig. 2). This cross-section represents the corresponding region of the descending colon in the 10-mm. embryo described above (fig. 1). In addition to the elongation of the nuclei, the cytoplasm is drawn out into a fine membrane between the separated nuclei. At the same time that the peritoneal epithelium is elongated, the epithelial tube is seen to have grown double in size, whereas the mesenchyme has only increased one-half that of the former stage observed.

The lumen of the epithelial tube is directed more transverse than vertical to the long axis of the gut. The lining cells appear to be overcrowding at the lower pole of the lumen due to rapid mitosis. This condition gives a stratified appearance to the epithelium. This rapid mitosis constantly causes an increase of free surface, and consequently the lumen rapidly dilates in width.

Concomitant with the rapid increase in width of the epithelial tube, there is observed a change in shape and rearrangement of the surrounding mesenchymal cells. The nuclei and surrounding granular protoplasm become elongated in a definite direction. Instead of the irregular arrangement characterizing the oval nuclei and stellate cytoplasm before, there is now observed a definite tendency for the cells to form concentric layers. This tendency is more marked in the midzone of the mesenchyme between the epithelial basement membrane and the outer simple epithelial peritoneum. In this midregion there is a condensation

more definite at the upper (fig. 2) than at the lower pole of the epithelial tube and greater in either polar region than on the lateral aspects of the tube.

With a further absolute increase in diameter of the epithelial tube (fig. 3) over that of the intestinal wall, the smooth muscle elements become more elongated, flattened, and spindle-shaped, and the definitive inner circular smooth muscle layer becomes more clearly defined out of its former nebulous state (fig. 2). By actual measurement with the filar micrometer, the intestinal wall is seen to become thinner as the epithelial tube constantly increases in size. The embryo is now approximately 20 mm. in length, and during this period it is convincingly seen that the long axis of the elongated nuclei are arranged along the paths of concentric circles. The longitudinal granular fibrils are likewise arranged in this concentric manner.

With the constant increase in width of the epithelial tube there is a progressively greater and greater elongation of the muscle elements nuclei and granular fibrils. These fibrils branch and anastomose with neighboring fibrils, and constantly maintain the original continuity of the protoplasmic syncytium. With the ever-increasing tension of the fibrils there is a progressive loss of water and increase in viscosity.[1] Definite physicochemical changes take place in the granular fibrils resulting in condensation and fusion of the granules into a continuous coarse irregular strand. Near the nuclei the swellings upon the strand are marked, but toward the poles of the nuclei the fibrils are more attenuated.

As formerly reported by McGill, there is the same tendency in the development of the colonic muscles to form coarse and fine myofibrils as detected in the oesophagus. These fibrils are of variable length and run through several neighboring cells in many cases. The coarse and fine granular fibrils are seen side by side. The coarser ones being primarily located at the periphery of the ill-defined spindle cell, whereas the finer granular myofibrils are located more internally and nearer to the nucleus. Between the fibrils more or less undifferentiated granular cytoplasm persists.

[1] The chemical changes in myogenesis will be reported later with my colleague in biochemistry, Victor E. Levine.

In embryos, between 24 and 46 mm., the descending colon increases rapidly in length. Peripherad to the inner smooth-muscle coat there is found the beginning of elongation of cells similar to that described for the inner smooth-muscle coat. Similar changes in shape and arrangement of the components take place, however, in a longitudinal rather than in a transverse plane. At first this layer is more or less uniform throughout (figs. 3 and 4), but there is soon detected a greater proliferation of cells immediately underlying the dorsal mesentery. This aggregation of cells represents the inception of the longitudinal mesenteric taenia coli band of fibrils. This is definitely seen in figure 6.

The initial genesis of the mesenteric taenia coli before the other bands appear is significant. If we remember that this location represents the outer curvature of a coiled tube in the process of rapid formation, it is readily seen that more definite tension of differential growth is exerted at this location. These bands are more definitely developed nearer the ileocecal valve. The dynamics involved will be considered later.

The longitudinal muscle, however, is only slightly developed at 28 mm., and at 45 mm. is not as conspicuous as the myenteric Auerbach's plexus. This plexus is located between the well-developed circular smooth-muscle coat and the attenuated outer longitudinal-muscle coat. The nerve plexus at these stages 10 to 46 mm. is composed of a continuous layer of groups of cells with crowded nuclei and many non-medullated fibers.

The inner submucous plexus of Meissner is not as prominent as the outer one. It is similarly constructed, although it contains fewer and much smaller ganglia and the meshes of the plexus are much finer. The terminal nerve fibers were traced to the epithelium and between the epithelial cells at 46-mm. stage. The plexus first appears along the inner border of the inner circular coat.

The muscularis mucosa is not differentiated at 45 mm. The lymphatic channels, however, are abundant at 32 mm. along the line of the mesenteric attachment. Lymphatic nodules are not formed, on the other hand, in the submucosa until the 150-mm. stage is reached.

The lumen of the descending colon is patent throughout development; no sign of atresia is observed. Between the 10- and 14-mm. stages small vacuoles were found, but no diverticulae are seen. At 10 and 14 mm. the colon is round or slightly elliptical in shape, gradually enlarging toward the cloaca. The lumen possess in the earliest stages a shape comparable to that of the entire tube. Between 53- and 46-mm. stages, however, lateral, evaginations are developed which give the lumen a crucial instead of a round or elliptical appearance. These evaginations push out at the lateral aspects where the circular muscle is least developed, along lines of least resistance. At the dorsal and ventral poles of the lumen the smooth muscle forms a thicker layer than on the lateral aspects. In addition, resistance is still further increased by the formation of the longitudinal mesenteric taenia along the dorsal, attached margin of the descending colon.

GROWTH MOTIVE FORCE IN INTESTINAL DEVELOPMENT

In the inorganic world that which produces motion or pressure is considered as due to a force. This entity has already been defined. One result of its action on an elastic body, namely, a strain, should now be considered. This is imperative, for if mechanical forces are at work on organic matter they tend to produce similar results as those acting upon inert matter. Too frequently the term self-differentiation is applied to alteration of form and internal structure of developing cells without searching the immediate environment of the specializing cells or syncytium to ascertain whether or not these changes are attributable to forces outside of the differentiating zone. This applies particularly to the differentiation of bone and muscle tissue. If a cell changes in form successively through the spherical, ellipsoid, and spindle stages it undergoes a strain. A strain is usually due to an external force which elicits internal reacting stresses in the body acted upon. Cytological differentiation is frequently a manifestation of these internal reacting stresses.

It will prove to be an illuminating study to search for the cellular forces outside of the immediate differentiating zone under

observation. This search necessitates lower magnifications in order to enlarge our field of view. Heretofore cytological differentiation has been studied per se with magnifications of 1000 to 2000 diameters which considerably reduces our range of view. The higher magnifications are profitable in revealing cytological detail, but the interpretation of the process is lost unless in conjunction with the higher, intermediate magnifications are used. By employing all possible magnifications of the microscope in connection with naked-eye studies we are less likely to lose the forest for the trees. Such a method is likely to reveal the interaction of related developing parts. Before applying this method it will be of advantage to consider briefly the different types of strain with which we are concerned.

DEFINITION AND CLASSIFICATION OF STRAINS

Elastic bodies are those in which a change takes place in the relative positions of their parts in contradistinction to rigid bodies in which no change occurs in the relative positions of their parts. Elastic bodies may suffer changes in their size or shape. Any definite alteration in the form or dimensions of an elastic body is called a strain.

This fact may be brought out in the following illustration: A rod which becomes longer or shorter is strained. Water when compressed is strained. A stone, beam, or mass of metal in a building or in a piece of framework, if condensed or dilated in any direction or bent, twisted or distorted in any way is said to experience a strain. A ship is said to 'strain' if, in launching or when working in a heavy sea, its different parts experience relative motions.

The simplest strain is a linear one. The stretching of an elastic cord is an example. This strain is called homogeneous when every portion of the cord has its length changed in the same ratio, so that the ratio of the initial to the final length of each part is the same as this ratio for the whole. The ratio of the final to the initial length is called the ratio of the strain; it represents evidently the quantity by which the initial length must be multiplied to obtain the final length. The elongation is the

ratio of the change in the length to the initial length. A negative elongation, or shortening, is called a compression. A positive elongation, or lengthening, is called a tension.

When all lines in a body parallel to a certain direction are changed in the same ratio, and no lines perpendicular to these are changed either in length or direction, the body suffers a strain of simple elongation. If, however, a second set of lines at right angles to these also suffer such a change, then there is elongation in two perpendicular directions; and if these lines are all in the same plane, the strain is a surface strain. A square elastic sheet, if the longation be e in a direction parallel to one edge, and e' parallel to another, will be converted by the strain into a rectangular sheet, the sides of which are proportional to the strain-ratios. Evidently two equal and parallel lines drawn on the square will remain equal and parallel after the change in form; and the strain will be homogeneous. If the elastic sheet be circular, the strain will change the circle into an ellipse, the two perpendicular directions which remain perpendicular after the strain becoming the axis of the ellipse. If these lines remain parallel to their original directions, the elongations take place along them and the strain is called a pure strain. If not, the strain is compounded of a pure strain and a rotation.

As seen above, the principal axis of a strain is the principal axis of the ellipse into which the strain converts a circle. If the increase of length along one such principal axis is equal to the decrease of length along the other principal axis, the strain under these circumstances is called a shear. Evidently in a shear the area of the plane itself remains unaltered. Any plane figure may be converted into a strained figure; that is, the shearing strain may be produced simply by fixing one of its sides, and moving all lines parallel to this fixed side in their own directions, through spaces which are proportional distances from this fixed line. The amount of this sliding motion which takes place between lines which are unit distance apart is called the amount of shear.

When a solid body undergoes a strain, a change may take place in its dimensions in one or more of three perpendicular directions. If the strain is such that all parallel lines within it are altered in

length in the same ratio, the strain is called a uniform or homogeneous strain, as previously pointed out. Thus, for example, a sphere when subjected to strain is converted into an ellipsoid, a solid every plane action of which is an ellipse. This ellipsoid is called a strain-ellipsoid. In any homogeneous strain of a solid body there are three directions at right angles to one another, which remain perpendicular after the strain. These directions are those of the three principal axes of the strain-ellipsoid.

Along one of these directions the elongation is greater and along another less than along any other direction in the body. Along the remaining one the elongation is intermediate. The principal axis of a strain is the principal axis of the ellipsoid into which it converts a sphere. The principal elongations of a strain are the elongations in the direction of its principal axis. According to Thomson and Tait, "Any strain may be viewed as compounded of a uniform dilatation in all directions, superimposed on a simple elongation in the direction of one principal axes, superimposed on a simple shear in the plane of the other two principal axes." With this brief account of the nature of strain we may now pass on to the consideration of the effects of differential growth in intestinal development.

The most rapidly growing part of the intestine is the epithelial tube (figs. 1 to 6). In 10- to 23-mm. embryos the descending colon grows relatively more rapid in diameter than in length. The increase in diameter is due primarily to the rapid growth of the entodermal epithelial tube and only partially to its surrounding mesenchymal cloak. The latter is relatively passive in growth with respect to the former. It is during this early increase in diameter that the inner smooth-muscle coat is in the process of formation. The mesenchymal cells are drawn out gradually in a definite series of concentric rings. These rings appear not unlike those of the planet Saturn and the annular nebula in Lyra.

A definite centripetal force is active in the rapid, spiral growth of the intestinal epithelial tube. The surrounding mesenchymal cells are thrown into a definite series of concentric rings accord-

ing to their various densities. Those possessing the greatest density joining the outer ring in the tangential path of the force, whereas the inner rings will be composed of bodies forming a gradient of decreasing densities. The cells forming the outer ring will be most elongated. Their water content decreases and viscosity increases.

As this concentric initial smooth-muscle layer becomes differentiated it tends to restrict the diametrical growth of the epithelial tube. The epithelial mitotic figures under this restriction shift their planes of division from a right angle to a parallel position with the smooth-muscle cells. This shifting results in an elongation of the intestine.

In embryos 25 to 40 mm. in length, the elongation of the descending colon is more rapid in growth than that of the diameter. It is during this period that the outer longitudinal muscular coat is in the process of formation. The rapid growth of the epithelial tube in length tends to elongate the peripheral undifferentiated mesenchymal cells which were not directly involved in the formation of the inner smooth muscular coat.

The differentiation of the outer longitudinal muscle coat therefore coincides, in time, with the rapid growth in length of the intestinal epithelium. The inner smooth-muscle coat, on the other hand, is formed during the period of the rapid growth of the intestinal epithelial tube in diameter.

In this study, the initial zone of rapid growth is found in the epithelial cells. Kinetic energy is transferred from within to the surrounding splanchnic mesenchyme by rapid spiral expansion of the entodermal epithelial tube. The less actively growing cells of the peripheral region of the intestinal wall are elongated. Later the potential energy of the elongated cells is transferred to those of the epithelium, resulting in a retardation of the growth in diameter. Immediately following this retardation of diametrical growth, the period of rapid growth of the intestine in length takes place. In this development, therefore, the factor of growth motive force, as a cause in the transference of kinetic and potential energy, is definitely detected.

Once the formation of the inner circular muscular rings is fairly established, a resistance to growth in width is encountered by the cells surrounding the rapidly dilating lumen. These cells then grow primarily along the path of least resistance in a longitudinal manner. At this stage the lontitudinal muscle cell, spherical in shape in figure 15, is elongated to a spindle-shape structure in figure 16.

In conclusion an interesting correlation in the development of the oesophagus in the human may be cited. This correlation was detected in the work of Jackson ('09) and in that of Keibel and Elze ('08). The former investigator studied the developmental topography of the oesophagus, the two latter the histogenesis of the oesophagus. Jackson states that the descent of the stomach is accompanied by a great elongation of the oesophagus. In a 9.4-mm. specimen the oesophagus measures 1.8 mm.; at this proportion, it should measure 4.3 mm. in an embryo 22.8 mm., but its actual length is found to be 8 mm. The year previously Keibel and Elze reported that the oesophagus in 12.5-mm. embryos show a circular but no longitudinal muscle layer; in 17-mm. embryos they find a circular layer with the longitudinal layer faintly indicated. The histogenesis of the outer longitudinal layer of the oesophagus as studied by Keibel and Elze coincides in time with the rapid elongation of the oesophagus, due to the descent of the stomach, as recorded by Jackson.

GROWTH MOTIVE FORCE IN LIMB DEVELOPMENT

The detailed description of the direct observations made on bone and skeletal muscular development will be reserved for a subsequent communication.

When the embryo is approximately 10 mm. in length, the first indication of the limb is a bud filled with a densely packed mass of uniform mesenchymal cells. Eventually, when the embryo is 14 mm. in length, a condensation of nuclei is detected in the center of the bud. This central condensation represents the primordial blastemal skeleton. It is the most rapidly moving or growing part of the limb. This is evident by the greater number

of mitotic figures and by the relative scarcity of cytoplasm and consequent closely compact nuclei. As the central core of the limb pushes forth more rapidly than that of the peripheral continuous mesenchymal cells, there is a tendency for the latter to be pulled out, stretched, or elongated by the former. The traction force of the rapidly growing appendicular core exerted upon the surrounding mesenchyme is the internal stimulus of a correlated part, resulting in the elongation of the nuclei of the premuscular mass in the direction of the blastemal skeletal growth.

From this direct observation that the cells of the premuscular mass are elongated in the direction of skeletal growth, we detect the objective evidence of the transference of kinetic energy from the zone of rapid growth to that of the relatively passive one. As differential growth continues and the growth motive force becomes more and more manifest, there is also detected a drawing out or stretching of the peripheral syncytial cytoplasm in the direction of the skeletal growth. This is first shown by the appearance of relatively parallel rows of discrete, isolated granules which represent differences in density of the cytoplasm due to the traction to which it is subjected. This is comparable to the tendency of a viscid substance, like egg albumen, to collect in droplets if placed between two glass slides when these are separated by a shearing force.

When the viscosity of the cytoplasm increases, on the other hand, with increased structural differentiation, these granules fuse and form a continuous condensed cytoplasmic strand known as the myofibril. At first this myofibril is coarse, but as the traction of skeletal growth continues it gives rise to numerous fibrils finer in texture. Thus, there is a direct proportional increase of the cytoplasmic components with continued skeletal growth. The formation of the embryonic skeletal muscles represents a definite reaction to the growth of the skeleton. These muscles tend to restrict the growth of the skeleton in length. This is manifested by an increasing condensation of the skeletal core.

This condensation is seen in the transition of the densely nucleated syncytial blastemal skeleton into the cartilaginous skeleton. The greater stability of the latter counteracts the deforma-

tion that would naturally occur in the former as the primitive muscles begin to contract. On the other hand, with increased skeletal condensation there is presented a more rigid base, and this in turn acts as a stimulus to more definite muscular differentiation. This is detected by direct observation in the splitting up of the uniform premuscular masses into its individual muscular components. Muscular forces become consequently more definitely applied and the definitive parts of the skeleton become more clearly outlined.

As the growth motive force of differential growth continues, the musculature becomes too vigorous for the cartilaginous base. The blastemal skeleton, as noted above, is supplanted by the cartilaginous one; there is now found another replacement of the cartilaginous by the osseous skeleton.

The changes which occur in a cartilaginous component of the skeleton, as the femur, in the formation of the more stable bony base, together with the concomitant muscular changes are as follows:

1. There is a bending of the cartilaginous femur with the convexity of the bow directed toward the M. quadriceps extensor. This deformation is incident to the contractility of the thigh musculature and the inception of the adduction action in rotation of the hind limb. This femoral strain is due to active and passive muscular stresses.

2. A strain fibrosis is detected on the weaker convex tensile aspect of the curved femur resulting in the histogenesis of the primary perichondrium which subsequently encircles the shaft.

3. Concomitant with increased muscular differentiation and subsequent activity there is a progressive dehydration, increase of viscosity, and increase of total acidity (table 1).

4. Inception of necrobiosis of the cartilage cells is seen immediately underlying the initial location of formation of the primary encapsulating perichondrium. This necrotic change is due to the diminished blood supply caused by the restricting action of the forming perichondrium. By injection and serial sectioning methods it is revealed that all capillaries and incipient discrete vesicles, precursors of capillaries, are peripherad to the primary perichondrium.

5. The vesiculated cartilage cells are arranged along definite curved tensile and compressile stress lines. Previous to the bending of the femur these cells are irregularly related to one another.

6. Hyalinization of cartilaginous matrix in the central zone of the curved femur is next observed.

7. Calcification then takes place in the hyalinized matrix. These intergrading steps in the condensation of the matrix is incident to increased muscular growth and functional activity and to the passive resistance of the musculature to skeletal elongation.

8. A subperiosteal osteogenetic and constricting cellular zone is begun immediately underlying the initial zone of fibrosis on the summit of the convexity of the curved femoral rod. This osteoblastic constriction quickly encircles the shaft. This is the

beginning of a consecutive series of bony deposition. This bony deposit is due to two factors: first, the stimulus of the functionally active thigh muscles and, second, the stimulus of the restriction to growth at the ends of the rapidly elongating femoral rod due to passive muscular resistance. These two factors tend to stimulate the formation of the osseous skeleton in replacing the calcified cartilaginous skeleton.

From the foregoing brief account it is desired to emphasize the following:

That there is a direct transference of kinetic energy from the more rapidly growing skeleton to the less actively growing primitive musculature and a reactive transference of potential energy from the latter to the former, tending to a condition of equilibration. With the inception of functional muscular activity there is a direct transference of kinetic energy from this tissue to the growing skeleton tending to retard or alter its motion or growth. The resistance passively manifested by the muscles is an additional factor tending to inhibit skeletal growth. This fact is also noted by Holl, Schomberg, and especially by Bardeen. In this case there is a transfer of potential energy due to position from the muscles to the skeleton. This active and passive play of the muscles on the cartilaginous base resulting in a condensation of a more stable framework and the consequent more definite effect of the latter on the former is due to a direct transference of energy by conduction. This transference of energy is of fundamental importance and is produced by the motive force of differential growth.

SUMMARY

Intestinal development

1. The region of most active mitosis, per mm. of cross-section, in the intestine is the entodermal epithelial tube. The mitotic figures primarily follow a path of a left-handed helix.

2. The region of least active or relatively passive growth per mm. cross-section is the mesenchyme, derived from the splanchnic mesoderm, surrounding the epithelial tube.

3. The rapid expansion due to epithelial growth in a rotating spiral manner of the intestinal lumen is greater than the activity manifest in the surrounding mesenchyme. This causes a pressure in the latter resulting in a flattening and an elongation of the mesenchymal cells. The successive changes in shape of these cells through the spherical, ellipsoidal, and spindle cellular phases are seen. The mesenchymal wall decreases in thickness, due to tension caused by epithelial tubular dilation.

4. The rotating spiral growth of the epithelial cells causes the formation of a series of mesenchymal cellular and fibrillar concentric rings due to the centripetal force of the former.

5. The inner circular smooth-muscle cells are differentiated in the outer more condensed margins of the ring. At these points the developing tensional stresses are greater than within the ring.

6. The tensional stresses to which the elongated strained mesenchymal cells are subjected appear to be a dynamic stimulus to smooth-muscle differentiation.

7. The inner circular smooth-muscle coat is the first one differentiated and is incident to the rapid growth of the epithelial tube in diameter. The kinetic energy of epithelial growth is transferred to the surrounding inner developing annular muscle. The latter soon tends to restrict the growth of the epithelial tube in diameter. The tube, pursuing the lines of least resistance, grows in length. During the period of rapid growth in length the outer longitudinal muscle coat is in the process of formation.

8. There is thus a definite interaction in intestinal development. We find evidence of a transference of kinetic energy from the zone of rapid growth of the epithelial tube to the less active mesenchymal wall resulting in the storage of potential energy due to position in the latter. Subsequently a transfer of resisting potential energy from the elongated mesenchymal cells to the rapidly growing cells of the epithelial tube. This tends to retard growth in diameter and to accelerate growth in length of the epithelial tube.

9. The developing musculature loses water. It increases in viscosity and total titratable acidity.

10. The increase in size of the granules in the mesenchyme is incident to the increase in viscosity. These granules are arranged in rows parallel to the long axis of the elongated nuclei. The same forces at play in nuclear elongation are involved in the formation of the rows of granular fibrils. The formation of the coarse continuous myofibrils occurs at a period when the viscosity and dehydration increases rapidly.

11. The following factors are intimately involved, therefore, in myogenesis:

a. Tensional stresses elicited by a force external to the differentiating myoblasts.

b. Loss of water.

c. Increase of viscosity.

d. Increase of total titratable acidity.

Limb development

1. The region of most active mitosis, per mm. cross-section in the limb is the skeletal core.

2. The region of least active or relatively passive mitosis, per mm. cross-section, is the surrounding continuous syncytial mesenchyme.

3. Potential energy is transferred from the rapidly growing blastemal skeleton resulting in an elongation or a homogeneous strain of the surrounding continuous syncytial mesenchyme.

4. With the rapid progressive extension of the blastemal skeleton more and more strain is put upon the elongating mesenchymal cells. The latter reacts upon the former continuously. There is a progressive condensation of the skeleton through the embryonal to the alveolar or cellular hyaline cartilage stages. This gradual condensation is detected during a period when the premuscular masses are being split into the individual muscles between 14- and 18-mm. stages.

5. Between 19 and 21 mm. the muscles become functionally active. Limb rotation is begun during this period.

6. The longitudinal continuous myofibrils are differentiated between 14- and 18-mm. stages.

7. As the growth motive force of differential growth continues, the musculature becomes too vigorous for the cartilaginous base. The blastemal skeleton, as noted above, is supplanted by the cartilaginous one; subsequently another replacement of the cartilaginous by the osseous skeleton occurs.

8. There is a direct transference of kinetic energy from the more rapidly growing skeleton to the less actively growing primitive musculature and a reactive transference of potential energy from the latter to the former, tending to a condition of equilibration. With the inception of functional muscular activity there is a direct transference of kinetic energy from this tissue to the growing skeleton tending to retard or alter its motion or growth. The resistance passively manifested by the muscles is an additional factor tending to inhibit skeletal elongation. This fact is also noted by Holl, Schomberg, and especially by Bardeen. In this case there is a transfer of potential energy due to position from the muscles to the skeleton. This active and passive play of the muscles on the cartilaginous base resulting in a condensation of a stable frame work and the consequently increased definite effect of the latter on the former is due to a direct transference of energy by conduction. This transference of energy is of fundamental importance and is produced by the motive force of differential growth.

General deductions from the study of myogenesis

Contractility is a fundamental property of primordial protoplasm. The protozoan, amoeba, possesses the property of contractility in all possible directions. The function of contraction in one definitive direction characterizes muscle tissue from that of undifferentiated and isolated organized particles of primordial protoplasm. What initiates the progressive series of physicochemical changes in primordial protoplasm resulting in an alteration of its attribute from non-specificity to specificity of direction of contractility? This question is answered as follows:

The primordial protoplasm before differentiating into muscle tissue, must be subjected to a certain minimal homogeneous and

ellipsoidal strain. This strain is objectively evident by an alteration of the form of the spherical nuclei into the ellipsoidal and spindle conditions and by an elongation of the granular cytoplasm into parallel granular and continuous fibrillae. The fibrillae are arranged along lines of internal and reacting tensional stresses. The ends of the primordial protoplasm, in tension, must be attached to supports of which one, at least, is mobile. The tensional stresses are reactions to simultaneous forces extrinsic to the zone of myogenesis. The external forces cause a progressive divergence or separation of the mobile supports to which the primordial protoplasm is attached. Therefore, muscle tissue is not self-differentiating, but is dependent upon an external dynamic stimulus. As regards smooth and skeletal muscles, this stimulus is the motive force of differential growth.

Growth motive force is any agency which tends to produce a transfer of kinetic energy, from an active to a less active group of cells, and of potential energy from a less active to an active group, in a cellular field of differential growth until equilibrium is established.

Whether or not the end-product in muscular formation will be of the smooth or cross-striated type depends upon the intensity of the stimulus of tensional stresses to which the mesenchyme is subjected. The genesis and maintenance of muscle tissue represents a resultant or equilibration of converging factors which are active and formative during development. One of these factors is the tensional stresses to which the mesenchyme is subjected by a force extrinsic to the differentiating zone. In subsequent involution or degeneration of muscular tissue, during the prenatal or postnatal periods, this equilibrium is upset by altering or destroying the tensional reacting stress.

It is a pleasure to record my grateful acknowledgment to my former chief, Dr. H. Von W. Schulte, of Creighton University, for his encouragement, helpful interest and suggestions, and for the opportunities he has extended to me in order to complete this part of my study on bone and muscle development.

I wish also to express my indebtedness to Mr. M. W. Murphy, manager of the Cudahy Packing Company; Dr. O. A. Edwards, private veterinarian and supervisor of the Swift Packing Company, and to Mr. L. A. Orchard, superintendent of the Armour Packing Company, South Side, Omaha, for their courtesies and generous permission in allowing me to obtain unlimited numbers of pig embryos for this study.

For the beautiful clear-cut illustrations, my thanks are due to Madame Helen Ziska.

Finally, for the ever ready help in completing this work, I owe my lasting gratitude to my wife.

PLATE 3

EXPLANATION OF FIGURES

13 Longitudinal reconstruction of the cross-sections nos. 45 to 94. This figure together with the cross-sections represents a plotting of the exact location of mitosis in the epithelial tube. Figure 13 is depicted as a tube cut through the middorsal region at 12 o'clock and lying flat.

14 Represents figure 13 in graphic reconstruction; the flattened tube is folded up so that the edges of the middorsal cut are in apposition. The spiral paths of the mitotic figures are objectively evident. The apical region of the respective paths are globular. This globular end is always directed cephalad. The basal end of the spiral path is directed caudad. The front and back aspects of the paths, as well as the cylindrical reconstruction is represented by solid and broken lines respectively.

Sections 45 to 94 represent the cross sections of the epithelial tube of descending colon. Section 45 is caudad; 94 is cephalad. The circles are numbered like a clock. Within the area enclosed by the two circles the dots are seen which represent the position and number of the mitotic figures. The arrows represent the direction of the spiral mitotic path which is seen to be right-handed. The predominant path, however, is left-handed. The large intestine of twenty animals was plotted. In only one was the mitotic path found to present a dexiotropic rotation.

Resumen por el autor, Oscar V. Batson.
Universidad de San Luis.

Deselectrificación de las cintas de parafina por medio de la corriente de alta frecuencia.

La cinta de parafina, al separarse de la navaja, con frecuecia se mueve, se adhiere a la navaja o es atraida por los objetos cercanos. Esta dificultad, conocida generalmente como electrificación, es muy molesta cuando se cortan secciones seriadas en tiempo frio y seco. La carga estática es de caracter negativo y está localizada en el tejido y no en la parafina. Esta carga se debe al rozamiento de la navaja sobre el tejido, porque si se corta un bloque de parafina sin tejido contenido en ella, no se produce cinta electrificada. La carga eléctrica puede suprimirse y prevenirse satisfactoriamente ionizando el aire ambiente por medio de un aparato portátil de alta frecuencia del tipo de "rayos violetas." Se frota el microtomo con esmeril, se coloca oropel sobre el soporte de la navaja y se sustituye el electrodo de vacío del aparato de alta frecuencia, por una barra envuelta en oropel. El electrodo de oropel se dispone de tal modo que la descarga de la brocha tenga lugar a través del área que recorre la cinta al ser producida por la navaja. El aparato debe mantenerse en marcha mientras se corte el tejido.

DE-ELECTRIFICATION OF PARAFFIN RIBBON BY MEANS OF HIGH-FREQUENCY CURRENT

OSCAR V. BATSON

Department of Anatomy, Saint Louis University

Electrification of the paraffin ribbon, particularly on the high-speed rotray microtome, has been responsible for the great difficulties in serial work, particularly in cold, dry weather. Various methods of eliminating the trouble have been tried with indifferent success.

The problem was analyzed, first, as to the nature of the electrification; second, the source and reason for a collection of the charge; third, a means of discharging the electricity as it is formed.

The nature of the charge was determined by means of the electrophorus. The charge on the metal plate of the electrophorus is positive. The electrified paraffin ribbon is attracted to the metal plate of the electrophorus (positive) through a distance of several inches and is conversely repelled by the wax plate (negative). A ribbon possessing no charge is affected but little, so the charge on an electrified ribbon may therefore be said to be a negative one.

The electrification of the ribbon comes about through the friction of the block on the knife and does not occur when paraffin alone is cut. Each section produces a certain amount of frictional electricity, and once a charge is formed, the paraffin as a non-conductor prevents its escape except into the air, and the escape into the air is dependent on the ionization of the gas particles to carry the charge.

The solution for a de-electrification of the ribbon would therefore resolve itself into terms of air ionization to permit a discharge of the electricity as it is formed. This was first attempted by using carnotite at the suggestion of Prof. Hermann Schlundt, of the University of Missouri. A bell jar containing several ounces of radio-active carnotite was placed over the microtome and knife so that the 'active deposit' might accumulate. The

experiment proved unsuccessful, although an electrified ribbon lost its charge in one-fifth the normal time when exposed to carnotite.

The following procedure, however, has proved quite successful. A portable 'violet ray' high-frequency apparatus is employed, substituting for the usual vacuum electrode a rod of wood, 8 inches long, closely wound with wire-cored Christmas-tree tinsel. The idea of using tinsel must be credited to Dr. T. G. Lee, of the University of Minnesota. The apparatus was clamped in position so that the tinsel electrode stood parallel to the knife edge and about 2 inches in front of and above it. Additional tinsel was placed on the block holder and the knife supports. The microtome was grounded to a water pipe. The distance was adjusted to give a brush discharge, i.e., a distance beyond the possibility of a spark discharge, and the vibrator was set so as to give a faint purple glow from the electrode in a darkened room.

Under these conditions, bits of previously electrified ribbon, adhering to the knife support and block, immediately dropped to the table. No electrification of the ribbon occurred with the microtome running rapidly, while the brush discharge was taking place. Curling of the ribbon recurred immediately when the current was turned off. Checking on the electrophorus, it was found that both positive and negative plates were discharged by being introduced into the high-frequency field.

CONCLUSIONS

1. Electrification of paraffin ribbon is due to a negative charge which results from the friction of the tissue on the knife. It accumulates because of an insufficient ionization of surrounding air.

2. The charge can be completely and satisfactorily removed by ionizing the surrounding air with a portable high-frequency apparatus with tinsel electrodes, and grounding the microtome.

3. The distance of the tinsel electrodes must be adjusted to give a faint brush discharge.

4. The stream of the current is through the microtome, and disagreeable sparking to the operator is absent. A slight odor of ozone is neither disagreeable nor harmful.

Resumen por el autor, Henry Bayon.
Universidad Tulane, Nueva Orleans.

Un caso de membrana costocoracoide osificada fusionada con la clavícula.

El sujeto objeto de este trabajo era un varón negro, de musculatura bien desarrollada, y presenta al reflejar el pectoral mayor una placa cuadrilátera de hueso que se articula con el esternón y se extiende lateralmente hacia arriba hasta una distancia de media pulgada del proceso coracoides, con el cual está unido por medio de una banda fibrosa. El hueso está unido con la clavicula, que forma su borde superior redondeado y ensanchado; el músculo subelavio falta y el pectoral menor se inserta en el extremo distal del hueso anormal. La indicación de mi asociado, Dr. Baker, acerca de la posible conexión del hueso descrito con alguna anormalidad de la cintura pectoral es probablemente correcta. En la rana toro, Rana catesbiana, el hueso coracoides se extiende desde la escápula hasta el esternón y está dividido en dos segmentos: Una ancha placa de hueso debajo, que es el coracoides propriamente dicho, y una barra delgada encima, el procoracoides, que representa la clavícula. En el desarrollo ontogénico de la clavícula de los mamíferos el cartílago en que aparece después el centro primario de osificación se deriva del coracoides primitivo. Plr consiguiente, es probable que el hueso anormal hallado corresponda al coracoides primitivo fusionado con sus derivados, es decir, con la membrana costocoracoide y la clavícula. Huntington cita la presencia de uno o dos nódulos cartilaginosos en la membrana costocoracoide. En el sujeto descrito en este trabajo la mayor parte de la membrana costocoracoide (fascia coracoclavicular) y el músculo subelavio se han osificado. Una prueba mas evidente de la identidad del hueso con el ligamento costocoracoides y la membrana es su perforación por la vena cefálica, cuya desembocadura en la vena axilar, es por otro lado normal.

A CASE OF OSSIFIED COSTOCORACOID MEMBRANE FUSED WITH THE CLAVICLE

HENRY BAYON

Department of Anatomy, Tulane University

ONE FIGURE

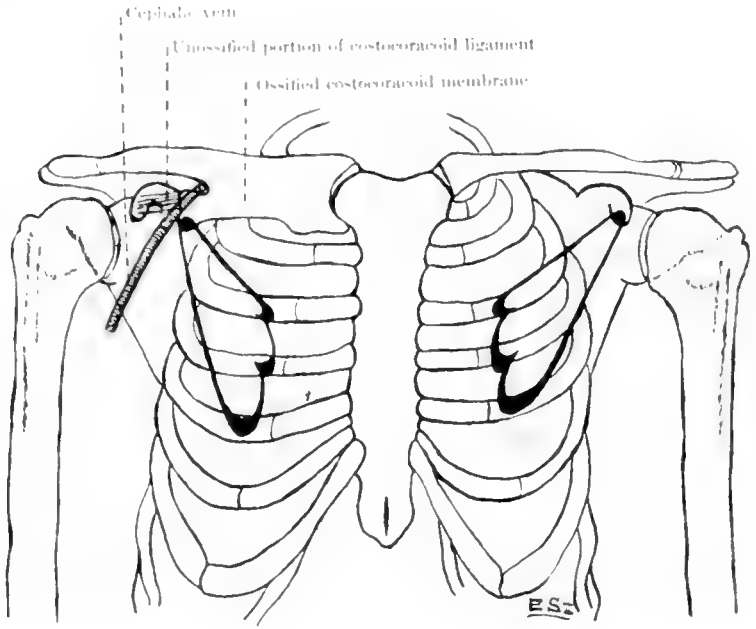
The subject, a negro male, with excellent muscular development, presents after reflecting the pectoralis major a quadrilateral plate of bone articulating with the sternum and extending lateralward to above half an inch from the coracoid process, to which it is united by a fibrous band. The bone is fused with the clavicle, which forms its upper rounded and expanded border; the subclavius muscle is absent and the pectoralis minor inserts at the distal end of the abnormal bone. The suggestion of Doctor Baker, my associate, that the condition might be connected with some abnormality of the pectoral girdle is probably quite correct.

In Rana catesbiana, bullfrog, the coracoid bone extends from the scapula to the sternum and is divided into two segments: a broad plate of bone below, the coracoid proper, and a slender bar above, the procoracoid, representative of the clavicle.

In the ontogenetic development of the mammalian clavicle the cartilage in which the primary center of ossification is further developed is derived from the primitive coracoid. It is consequently quite probable that the abnormal bone here found corresponds to the primitive coracoid fused with its derivatives, namely, the clavicle and the costocoracoid membrane.

Huntington cites the presence of one or two cartilaginous nodules in the costocoracoid membrane. In the subject here presented the greater part of the costocoracoid membrane (coracoclavicular fascia) and the subclavius muscle have undergone ossification. A further evidence of the identity of the bone with

the costocoracoid ligament and membrane is its perforation by the cephalic vein, which otherwise normally drains in the axillary vein.



Resumen por el autor, Henry Bayon.
Universidad Tulane, Nueva Orleans.

Diferencias raciales y sexuales del apéndice vermiforme.

El objeto del presente trabajo es el describir las diferencias que existen entre el apéndice del blanco y del negro, las cuales podrían explicar la mayor susceptibilidad para la apendicitis en la raza blanca, si es que existe tal susceptibilidad. Las observaciones efectuadas incluyen diferencias sexuales y raciales en el tamaño, musculatura, número relativo de linfocitos y criptas, y vascularización del órgano. Del exámen microscópico de secciones transversales de cien apéndices se deduce que las diferencias mas salientes en las dos razas se refieren al número mas elevado de linfocitos en el apéndice del hombre blanco y la mayor riqueza vascular del mismo órgano en el negro Las estadísticas del Hospital de Caridad de Nueva Orleans, que fueron consultadas incidentalmente, parecen confirmar una susceptibilidad mayor de la raza blanca a las enfermedades de otros órganos linfáticos, tales como las tónsilas palatinas y faríngeas.

BY THE BIBLIOGRAPHIC SERVICE, JULY 26

RACIAL AND SEXUAL DIFFERENCES IN THE APPENDIX VERMIFORMIS

HENRY BAYON

Department of Anatomy of Tulane University

About thirty years ago the appendix had practically no history, either physiological or pathological.

Howard Kelly, in his extensive work on the vermiform appendix and its diseases, recalls that only in 1824 was the appendix recognized as an organ susceptible to disease arising primarily in its own structure, although mention was made of isolated cases such as Mestivier's recorded in 1759 in which a postmortem examination revealed a pin concealed in the appendix, which had caused inflammation resulting in the death of the patient. This and other similar cases related in Kelly's work show that even in the eighteenth century the appendix was recognized as susceptible to inflammatory lesions, but it was not until 1886 that the appendix was placed in the category of organs susceptible to surgical disease. From that time the daily harvest of appendices has steadily increased. At the beginning of that period we hear Frederick Treves, one of the pioneers of appendectomy, clamoring against the indiscriminate removal of the appendix, which he brands as a needless and illogical recklessness.

Since that time a number of speculative statements have appeared regarding the purpose of the appendix, usually more or less fanciful and sometimes positively grotesque. From the high office of abdominal tonsil we find it elsewhere relegated to the abject rôle of the ordinary mechanical grease cup. In studying the minute structure of the appendix, it is true that large numbers of lymphocyte accumulations are found within its walls, but at best these amount to little compared with similar accumulations found elsewhere in the intestinal canal and are in no way different from the solitary and aggregated lymphatic nodules.

Needless to say that the grease-cup theory finds no support from whatever angle the organ is viewed. It evidently originated in 1749 from an old theory of J. Vosse, who claimed that the glands of the cecum were not sufficient to moisten its contents and that the function of the appendix was to provide additional secretion.

It is not the purpose of the present study, however, to discuss the function of the appendix nor the conditions which call for its removal. It was undertaken with a view to possible differences in structure, both as to race and as to sex.

In considering disease of the appendix, the following questions suggested themselves: Is appendicitis more frequent in the white race than in the negro? Is the disease more prevalent in one or the other of the sexes? And if there are racial and sexual differences, is there anything in the structure of the appendix to account for such differences?

The first question, if records and surgical experience are given consideration, is answered decidedly in the affirmative. The statistics, however, on this, as unfortunately on a great many other subjects, are totally unreliable, even though tabulated intelligently and in good faith.

The eagerness displayed by the medical profession in coming before the public, both in print and in lecture, no doubt in a great many instances with very laudable intent and good effect, places within reach of the more intelligent layman much of the interpretation of his own ills and pains. He seldom ignores the signs and symptoms of appendicitis. As a result, the first tinge of pain in the right iliac region will sound a loud note of warning, followed by a rush to the surgeon, who at once proceeds to remove the appendix, in which postoperative examination frequently reveals little or no inflammatory change. This statement, however, is made with due regard to surgical prudence which takes no chances in a condition where prompt treatment means so much to the patient's safety. At this juncture it may not be inappropriate to refer to the opinion so frequently expressed, that appendicitis is on the increase. That the number of appendectomies has increased there can be no question, but that appendicitis is increasing is more than doubtful.

In contrast with the alertness of the better classes and their readiness to part with an offending organ, is the ignorance and apathy of the poor negro concerning his disease and the counter-indifference of his medical attendant. Acute indigestion or heart failure are convenient and ready forms for his death certificate. Acute gangrenous appendicitis may have caused his death, but his tardiness in seeking medical aid or the lack of interest of his doctor, who comes in when the patient is dying or dead, are in many instances responsible for the error in diagnosis. Hence a possible flaw when records are considered, in passing judgment as to the racial susceptibility to appendicitis.

But if statistics are negative in deciding susceptibility, might there not be some structural peculiarity which would make certain appendices more vulnerable than others? Some time ago, in a casual examination of appendices in the dissecting-room, I was struck with the stout musculature of the negro organ as compared with the flabby membranous appearance of the white appendix. Obviously, a fecal stone or a foreign body would have far less chance of becoming impacted or retained in a robustly muscular appendix with active peristalsis possible than in one whose weaker walls would not only fail to rid the organ of its offending contents, but in consequence of the organ's easier distention would favor the storing up of enormous numbers of pathogenic bacteria.

Hoping to arrive at some tangible facts regarding structure which might cast some light on racial and sexual peculiarities, I have examined 100 appendices and tabulated them according to race and sex. The specimens employed comprised 53 negro appendices, 31 male and 22 female, and 47 white appendices, 11 male and 36 female.

METHOD OF PREPARATION

The appendices were at first fixed in 10 per cent solution formalin, then mordanted in the following fluid:

35 per cent aqueous solution bichromate of potash	92
Formalin (40 per cent formaldehyde)	4
Glacial acetic acid	5

The appendices were then imbedded and sectioned in celloidin, stained by Delafield's hematoxylin and counterstained in eosin.

LEVELS AT WHICH STAINED SECTIONS WERE TAKEN

In order to obtain more reliable data, dissecting-room appendices were not considered. Appendices so diseased as to show disorganization or destruction of their tissues were avoided. Only recently removed appendices gathered from autopsies and abdominal operations at Charity Hospital and Touro Infirmary of this city and preserved in formalin solution were used. The material included twenty-five slides of cross-sectioned appendices borrowed from the pathological department of Charity Hospital. Each appendix was measured in length and in width and cross-sectioned two or three times from base toward the apex.

The average length, in all cases considered regardless of race or sex, was 9.2 cm. in seventy-one specimens (table 1) and the average width 6.2 mm. in ninety-eight specimens. The length and width of the 100 appendices were not all available. The length was not mentioned in the histories of the twenty-five Charity Hospital slides, and in four of the specimens prepared by myself part of the organ was missing. The width was taken from the mounted cross-sections in all cases except in two, the specimens having been previously opened by the pathologist for inspection.

Tables 2 and 3 show a sexual difference in favor of the male, giving an average of 9.6 cm. (length) and 6.5 mm. (width) in the male against 8.7 cm. (length) and 6 mm. (width) in the female. tables 4 and 5, the racial difference (in the two tables) show an average of 7 cm. (length) and 6.5 mm. (width) in the white and 11.3 cm. (length) and 6 mm. (width) in the negro.

It may well be objected that in tables 2, 3, 4, and 5 the inferences must be unreliable, the number of cases being too restricted. In table 1, however, which deals with the average length of the appendix, regardless of race or sex, the same objection does not prevail. The slight difference in size between the male and female appendix is all that might have been expected, although that,

together with racial differences, would seem to offer no solution to the problem at issue, namely, structural peculiarity bearing on susceptibility to inflammation. The tabulations were simply included as a matter of general interest.

The field which seemed most promising was the microscopic survey of the transverse sections. This consisted in measuring the thickness of the longitudinal and circular muscular tunics expressed in terms of microns together with noting the relative amount of lymphocytes, fat and crypts and the vascularity of each appendix, classifying the specimens into three categories, rich, moderate and poor, as indicated in table 6.

TABLE 6

Based upon 100 specimens

	MUSCULATURE IN MICRONS		LYMPHOCYTES			FAT			CRYPTS			VASCULARITY		
	Long	Circular	Rich	Moderate	Poor	Rich	Moderate	Poor	Rich	Moderate	Poor	Rich	Moderate	Poor
			per cent	*per cent*	*per cent*	*per cent*	*per cent*	*per cent*	*per cent*	*per cent*	*per cent*	*per cent*	*per cent*	*per cent*
N. M.—31 C.	247.6	350.8	16	22	62	23	32	45	19	55	26	64	29	7
N. F.—22 C.	270.4	375.3	14	64	22	41	41	18	14	36	50	54	27	19
W. M.—41 C.	270.4	435.9	64	18	18	27	55	18	36	9	65	18	18	64
W. F.—36 C.	241.2	392.8	47	44	9	59	29	12	62	23	15	16	21	73

A glance at the figures disproves the first impression regarding musculature. It is, therefore, quite evident that immunity from appendicitis in the negro, if such exists, cannot be accounted for by a stronger peristaltic wave. Indeed, the measurements show a preponderance of muscular tissue in the white appendix.

The racial and sexual differences in the percentage of fat conform with the general distribution of fat elsewhere in the sexes and in the two races. The negro as a race carries less fat in the average than the white, and in both races the female carries more than the male.

The difference in the number of crypts retained is decidedly in favor of the white appendix. This would seem to indicate less

susceptibility to inflammation. Hence, the study of structure in this particular feature, far from confirming disease statistics, offers decided opposition and is quite suggestive to the reverse.

The difficulty, however, presented by the crypts is offset very singularly by the findings regarding both the lymphocytes and vascularity. In the white appendices, 64 per cent male and 47 per cent female were found rich in lymphocytes, and 18 per cent male and 16 per cent female were found rich in vascularity. Comparing this with the findings for the negro appendix, 16 per cent male and 14 per cent female were rich in lymphocytes and 64 per cent male and 54 per cent female were found rich in vascularity.

In the cases here examined the ratio in the two races between lymphocytes and vascularity is inverted—the richer in lymphocytes, the poorer the vascularity seems a characteristic of the white appendix, whereas the reverse obtains for the negro appendix, in which the scarcity of lymphocytes corresponds with rich vascularity. From the figures the fact stands out that the white appendix is richly lymphatic and poorly vascular and the negro organ just the reverse.

In the white appendix are found two conditions predisposing to inflammation more especially of the gangrenous type—a rich supply of lymphocytes indicating predisposition to inflammation and poor vascularity favorable to gangrenous changes.

It may be objected that since the cases were tabulated regardless of health or disease, the prevalence of the appendices rich in lymphocytes might result from inflammatory action. The objection is met by the fact that, although in some cases operation was performed for appendicitis, in a great many other cases operation was performed for disease other than appendicitis, the appendectomy being performed simply as a matter of prudent routine in anticipation of possible future appendical trouble. But even if on that account, the high percentage of organs rich in lymphocytes found in the white cases be considered of negative value, the fact remains that these specimens show a low percentage of vascularity, and if inflammation alone could suggest increased lymphatic richness, it should also accentuate vascularity, which is quite contrary to the finding.

Racial differences in the appendix suggested that corresponding differences might also exist in other diseases of the lymphatic system. Statistical inquiry into the relative number of tonsil and adenoid disease in the two races demonstrated that in 4759 patients admitted into the Charity Hospital during the first three months of 1917, 2258 were negroes and 2501 were whites. In the 2258 negro cases there were 35 tonsil cases and 8 adenoid cases. In the 2501 white cases there were 95 tonsil cases and 21 adenoid cases.

Table 7 shows that the number of tonsil cases was more than twice as great in the white than in the negro and that the number of adenoid cases was twice as large in the white.

TABLE 7

	TONSIL CASES	ADENOID CASES
2258 negro patients	35 (0.015 per cent)	9 (0.004 per cent)
2501 white patients	95 (0.037 per cent)	21 (0.008 per cent)

In these tonsil and adenoid cases figures may hold out equivocal interpretation: we are well aware that more whites than blacks are prone to become nervous about health conditions and the same suggestion regarding the advisability of parting with the appendix prevails for tonsils and adenoids. It rests with the specialist whether the organs show sufficient evidence of disease to justify operation and the administration of an anesthetic—always a grave responsibility. Be that as it may, if each tonsilectomy and adenoidectomy means diseased palatine or pharyngeal tonsil, the unavoidable and indisputable inference is that tonsil and adenoid disease is more prevalent in the white than in the negro.

The same Charity Hospital records for the first three months of 1917 show a total of twenty-three negro cases of appendicitis against eighty-five white cases. With due allowance for the doubtful trustworthiness of statistics considered from the standpoint of their face value, it may be safely assumed that when viewed in the light of histological findings above submitted, they

are at least quite suggestive of greater susceptibility of the white race than the negro to appendicitis.

Differences in the lymphatic system of the white and negro races may also be inferred from the findings of Bean and Baker, which appear in the Journal of Physical Anthropology, vol. 2, no. 1, 1919, under the title of "Some Racial Characteristics of the Spleen Weight in Man." Over 1500 white and about the same number of negro spleens are considered, showing a decided difference in weight in favor of the white spleen.

These findings are well correlated to those submitted in the present study and seem to prove that the white race is more subject to lymphocytic stasis than the negro.

SUMMARY

1. The musculature of the white appendix is not weaker. Indeed, it seemed slightly stronger than that of the negro.
2. The female appendix is richer in fat than the male.
3. The white appendix is richer in crypts.
4. The white appendix is rich in lymphocytes and poor in vascularity and the negro appendix rich in vascularity and poor in lymphocytes.
5. The average size of the appendix is 9.2 cm. in length and 6.2 mm. in width.
6. The white appendix is shorter and wider than the negro appendix.
7. The male appendix is longer and wider than the female appendix.

HUMAN PARASITOLOGY, WITH NOTES ON BACTERIOLOGY, MYCOLOGY, LABORATORY DIAGNOSIS, HEMATOLOGY AND SEROLOGY, by DAMOS RIVAS, B. S. Biol., M.S., M.D., Ph.D., University of Pennsylvania, Illustrated. 716 pages, W. B. Saunders Company, Philadelphia, Pa. 1920.

EXTRACTS FROM PREFACE

A half century ago medicine was more an art than a science. The doors of American medical colleges stood wide open to welcome all who came as students, and if they showed a desire to learn, possessed enough elementary education to enable them to read their text-book and write their examination papers no questions were asked as to their acquaintance with the physical and biologic sciences.

There was no science of parasitology. Parasites were zoologic curiosities that occasionally intruded into the sphere of medical activity.

Now all has changed. The necessities of commerce have led to such extensive geographic explorations that the entire surface of the earth has been explored and charted. Ethnologic investigators have uncovered the location, life and habits of many formerly unknown peoples.

The general rapid advance of scientific knowledge, especially the progress of physics, chemistry and biology, inevitably reacted upon medicine, stimulating the scientific spirit, demanding research upon its obscure problems, and requiring a new type of student whose preparation for medicine must include at least an elementary knowledge of the collateral and fundamental sciences.

The author has for twenty years interested himself in parasitology and has had the good fortune to have studied in public health laboratories at home and abroad, and to have served on sanitary commissions. After years of teaching he now endeavors to bring together the facts of parasitology in a form suitable to the needs of the student and physician. The following pages reflect his personal experiences and present the facts of the subject in a form sufficiently brief to make it a text-book—the modern tendency is to be encyclopedic—and sufficiently full not to omit any important fact or method.

THE ANATOMICAL RECORD, VOL. 19, NO. 5
OCTOBER, 1920

Resumen por el autor, Carl G. Hartman.
Universidad de Texas.

Los fenómenos del parto en el opossum.

En oposición a lo que se cree generalmente, el embrión del opossum, al final del periodo de gestación, que dura diez dias, camina por sus propios esfuerzos desde el orificio vaginal hasta la bolsa marsupial, en la que encuentra la mama. La madre no ayuda al embrión durante su paso desde la vagina a la bolsa, pero le lame para despojarle del líquido coriónico, cuando sale por la vulva. Lo mismo que en el caso de las especies australianas Perameles y Dasyurus, descrito por Hill, los embriones alcanzan el canal vaginal medio no por los canales vaginales laterales, sino por un túnel que aparece de novo en el tejido conjuntivo situado entre la uretra y los canales vaginales laterales.

STUDIES IN THE DEVELOPMENT OF THE OPOSSUM DIDELPHYS VIRGINIANA L.[1]

V. THE PHENOMENA OF PARTURITION[2]

CARL G. HARTMAN
The University of Texas, School of Zoology

THE METHOD OF TRANSFER OF YOUNG TO THE POUCH

The literature

So far as the writer has been able to discover, there exists in the literature only one account of the actual birth of any marsupial, notwithstanding the abundance of opossums in America and the variety of all marsupial fauna in Australia. Nor does that foremost of all students of marsupial embryology, Prof. J. P. Hill, refer to this topic, although on one occasion ('00, p. 371) he killed a specimen of Dasyurus after "one only of the young had been born." Meigs ('47) and Selenka ('87) examined pouch young of the opossum immediately after birth, but made no observation on parturition.

The single recorded observation referred to is that of Dr. Middleton Michel, of South Carolina ('50), who, on January 28, 1847, witnessed the copulation of a pair of opossums, and fourteen days and seventeen hours later saw the birth of the foetuses. In order to show, however, that Doctor Michel failed to see the actual passage of the young to the pouch, two essential paragraphs on the point at issue are here quoted:

[1] Parts 1 and 2 (History of the early cleavage—Formation of the blastocyst) appeared in the Journal of Morphology, volume 27, number 1, March, 1916; and Parts 3 and 4 (Description of new material on maturation, cleavage and entoderm formation—The bilaminar blastocyst) appeared in the Journal of Morphology, volume 32, number 1, March, 1919. These four parts may be obtained from the publishers.

[2] Contributions from the School of Zoology, the University of Texas, no. 143.

The pregnant female was found standing on her hind legs; her body was much bent, and propped up against the corner of the cage; her muzzle in immediate contact with the cloacal opening, which was red, tumefied and distended; a young appeared at the opening, and was conveyed by the mother's mouth to the pouch, or perhaps was rather licked in, as her tongue seemed busily employed within, around and about the pouch.

The young are expelled first into the vaginal cul-de-sac, in which they remain for a short time, on the contraction of which they are forced along the vaginal canals one by one; parturition is thus very much prolonged, owing to the circuitous route which the young are obliged to take, and the delay thereby occasioned between the birth of each is the object of the peculiar modification of these parts in this animal, as it affords the requisite time employed in the conveyance of the young to the pouch and their adaptation to the teat.

It is quite clear from the language of this quotation that Doctor Michel did not actually witness the migration of the embryos and that he merely guessed at the method employed by the mother, since he was not sure whether she used her mouth or her tongue. It will, moreover, be shown below that Doctor Michel was also mistaken in presuming that the young at birth pass out by way of the lateral vaginal canals. The observations recorded below indicate that the marsupial female does not actually transfer the foetuses to the pouch and that Doctor Michel's interpretation, as well as the prevailing notion in accordance therewith, is not borne out by the facts.

Some preliminary observations

A series of observations and experiments during the last four or five breeding seasons of the opossum had enforced the conviction that the young reach the pouch and find the teat by their own efforts and are not placed on the teats by the mother's tongue or lips. Why should it be necessary, one may ask, in the absence of actual observation, to presume such undue skill and sensitivity in the adult when a pure instinctive reaction on the part of the young will suffice?

On several occasions I experimented with newly born pouch young, gently removing them from the teats to which they had firmly attached themselves by means of their powerful tongues.

I quote from my notes in one case (no. 301, experimented upon in the presence of Dr. C. H. Heuser, of The Wistar Institute, January 20, 1917):

> Female tied down and pouch opened. Young which were removed from teats crawled about, moving hands alternately, as in swimming. Were able to crawl among hairs and find teats by their own efforts. One specimen, removed three times, found teat each time and three others found teats after wandering about.

These experiments certainly argued strongly in favor of some little independence of action on the part of these 'embryos,' a term that Doctor Meigs ('47) would have us abandon when speaking of these "breathing, sanguiniferous, digesting pouch young."

On February 6, 1917, on opening specimen no. 402 under anesthesia, I was surprised to find a collapsed but very vascular uterus, as if birth had just taken place. This proved to be the case, for on removing the animal from the table I found that the entire litter of foetuses had been expelled during the operation. They were mostly still alive, entangled in foetal envelopes and immersed in the foetal fluid. To some of the foetuses the umbilicus was still attached; others were free, but no navel could be seen in any case. None of the foetuses, even after being freed of membranes and liquids, could crawl about, as they were apparently drowned in their own embryonic fluid. It seemed likely, therefore, that the embryos, on emerging from the vagina, need the assistance of the mother to lick away the fluid expelled from them, and this was later verified by actual observation.

Embryos near term were also removed from the uterus, freed of their envelopes, and allowed to crawl about over the mother, which they did for at least fifteen minutes.

On one occasion I removed one uterus three days before term (no. 131), and about the time that birth was to be expected from the remaining uterus I injected some pituitrin subcutaneously, hoping to witness parturition thus brought on. But owing to the fact that abortion had previously taken place, as was afterward learned, only mucus was extruded from the genital orifice.

It is interesting to note, however, that after the injection of pituitrin the female licked out the pouch at frequent intervals, an act which probably always precedes parturition.

The birth of the opossum

Specimen no. 443 was brought to the laboratory February 2, 1920, having been captured uninjured several nights before. She was a healthy female of medium size, and by palpation of the mammary glands, after the method which I have described at another place ('19, p. 24), I recognized her as pregnant and likely to give birth within several days. I removed her to my home, where she was kept under observation night and day, and the success which attended the undertaking is largely due to my wife's enthusiasm and perseverance.

The animal was placed just outside a window in a cage illuminated within by a red electric light, which arrangement was least disturbing to the animal as she was insulated against noises from within the room; the sight of persons moving about in the room caused little response on the part of the animal, but slight noises near the cage startled her greatly.

At 10:30 P.M., February 6, 1920, the animal showed signs of restlessness and soon began cleaning out the pouch, which she did about four times. Then began a short series of spasmodic contractions of the abdominal wall, after which she came to a sitting posture with legs extended. At no time did she stand on her hind legs, as Doctor Michel seems to have observed, for such a position is certainly strained and unnatural. I once had an opossum give birth while she was confined in a burlap sack in which she was carried to the laboratory. In this case it was assuredly impossible for her to stand on her hind legs during parturition.

After assuming the sitting posture, our specimen bent her body forward and licked the vulva; however, her position at this time was such that we could not see the embryos, which very likely passed into the pouch with the first licking of the genital opening. Hence we went to the outside where we could plainly hear her

lap up the chorionic fluid; then suddenly a tiny bit of flesh appeared at the vulva and scampered up over the entanglement of hair into the pouch to join the other foetuses, which now could be seen to have made the trip without our having observed them. Unerringly the embryo traveled by its own efforts; without any assistance on the mother's part, other than to free it of liquid on its first emergence into the world, this ten-day-old embryo, in appearance more like a worm than a mammal, is able, immediately upon release from its liquid medium, to crawl a full three inches over a difficult terrain. Indeed, it can do more: after it has arrived at the pouch it is able to find the nipple amid a forest of hair. This it must find—or perish.

Having now satisfied ourselves as to the manner in which the young opossum reaches the pouch, we etherized the female, hoping still to find some of the embryos within the genital tract. But it happened that we had witnessed the last of the litter make the journey. The pouch contained a squirming mass of eighteen red embryos of which twelve were attached, though thirteen might have been accommodated. The remainder were, of course, doomed to starvation. Even some of these unfortunates, however, held on with their mouths to a flap of skin or to the tip of a minute tail, while several continued to move about.

With the mother under the influence of ether, we now gently pulled off a number of embryos from the teats in order to test their reactions. The teats had already been drawn out from about a millimeter in height to double that length, doubtless by the traction of the embryo itself, for the bottom of the pouch certainly presented a busy scene with each member of the close-pressed litter engaged in very active breathing and sucking movements.

One detached young, placed near the vulva, crawled readily back into the pouch. Two or three others regained the teats after some delay, and one wanderer, which lost out in the first scramble, found a vacated teat and attached itself even after twenty minutes' delay, showing that the instinct to find the teat persists for some time. If the skin be tilted, the embryos, can

be made to travel upward and even away from the pouch, for they are negatively geotropic.

For locomotion the embryo employs a kind of 'overhand stroke,' as if swimming, the head swaying as far as possible to the side opposite the hand which is taking the propelling stroke. With each turn of the head the snout is touched to the mother's skin as if to test it out, and if the teat is touched, the embryo stops and at once takes hold.

It is thus apparent that the opossum embryo at birth possesses not only fairly well-developed respiratory and digestive systems, but that it has attained a neuromuscular development sufficient to enable it to find its place in the pouch where food and shelter await it.

The number of pouch young

Most female opossums possess thirteen teats, of which usually only the posterior eleven are functional. I have often found as many as eleven pouch young attached, but only in two cases as many as twelve. Doctor Meigs ('47) on one occasion found thirteen. I have seen litters consisting of fifteen, seventeen, and eighteen newly born young in the pouch, with as few as seven attached to teats, and have removed from pregnant uteri as many as twenty-two normal foetuses near term. Such overproduction with consequent mortality has already been pointed out for the opossum and other marsupials (Hill, '10, '11; Hartman, '19).

Folklore

In the popular mind the generation of no animal is so shrouded in mystery as that of the opossum. From New Jersey to Texas several beliefs are current which it might be well to state at this point.

There is a wide-spread notion that copulation takes place in the nostril of the female and that the 'fruit of conception' is blown into the pouch. This superstition rests upon two observed facts: first, that the opossum penis is dichotomous and, second, that the female licks out the pouch immediately prior to parturition.

Another notion is that the pouch young is organically connected with, or 'grown to,' the teat, in fact so intimately that bleeding results from the forced separation of the pouch young. Doctor Meigs ('47) already showed that this is not the case.

Doctor Meigs mentions and refutes the idea prevailing in his time that the pouch young produces a teat wherever it happens to take hold of the skin in the pouch.

Finally, it is often stated that the marsupial mother pumps milk into the pouch young. Whether or not this is true the writer does not know, but certain it is that from the very beginning the young opossum engages in active sucking movements.

THE PASSAGE OF THE FOETUSES FROM THE UTERUS

As is, of course, well known, the opossum, as a member of the order Marsupalia, possesses two uteri. These do not communicate posteriorly, but open each into a separate shallow cul de sac, on either side of a median partition. Each cul de sac communicates laterally with a loop, the 'lateral vaginal canal' (Hill, '97), which curves laterad, then caudad and mediad, until near the midline the two canals almost touch; and from this point backward they lie parallel until they empty into the 'median vaginal canal' (Hill, '97) or urogenital passage (Owen, '68). The lateral vaginal canals thus resemble two question marks placed face to face; the curved portions lie in the body cavity, the 'stems' are imbedded in the connective tissue of the urogenital strand. The urethra forms a third parallel tube, lying in the midline ventrad to the straight portion of the lateral vaginal canals and emptying with them into the median vaginal canal.

In two Australian species Hill (Parameles, Dasyurus; Hill, '98, '00) made the surprising discovery that the embryos at birth do not pass out through the lateral vaginal canals, but break through by a cleft-like rupture, the 'pseudovaginal canal,' directly into the median vaginal canal from the culdesac into which the os uteri opens. The new passage is described as a split in the connective tissue, at no time lined with epithelium and containing fragments of foetal membranes together with leucocytes and maternal blood clots.

I have on several occasions demonstrated in the opossum the existence of the pseudovaginal passage discovered by Hill. In specimen no. 402, already mentioned as aborting under an abdominal operation, one could follow a bloody trail direct into the median vaginal canal exactly as Hill had described it. The hemorrhage was less severe in no. 443, the birth of whose young has been described above, but the new passage was easily demonstrable. The organs were fixed in Bouin's fluid and sectioned. The findings are quite in accord with those of Hill. The pseudovaginal canal is seen to be simply a slit in connective tissue between the bladder and urethra ventrally and the caudal ends of the lateral vaginal canals dorsally. In formaldehyde preparations of the organs taken from non-pregnant females such a pseudovaginal passage can with great ease be pushed through; that is, the urethra may very readily be separated from the parts dorsal to it. It appears quite certain that the contraction of the abdominal and the uterine walls is sufficient to force the new passage at the time of birth.

The embryonic envelopes are partly retained within the uterus, a fact already noted by Osborn ('87) for the opossum, and partly scattered along the median vaginal canal. None were found in the lateral vaginal canals either by Osborn or by the writer. It is possible that an embryo may even drag parts or all of its foetal membranes to the exterior, in which case the mother may lick it free; but my only evidence on this point is the presence of the foetal membranes about many of the embryos in the case of one abortion.

The opossum should therefore be added to the list of marsupials which force the 'pseudovaginal canal' at parturition.

One might suppose from this that the lateral vaginal canals would possess a special function. The writer believes with Hill that they function as receptacula seminis, since in the marsupials several days elapse between copulation and ovulation. In the opossum the enlargement of the canal is one of the striking features of the prooestrus period. At oestrus they have attained an enormous size and are filled to turgidity with a thin, lymph-like fluid. Soon after ovulation they shrink almost to the resting

stage and are filled with cheesy masses of epithelial cells, which remind one of a similar phenomenon described by Stockard and Papanicolaou ('17) for the guinea-pig at oestrus.

ADDENDUM

Several months after the foregoing paper had been received by the editor of this journal the writer received a note from Dr. H. H. Donaldson, of The Wistar Institute, in which he stated that he had learned from Dr. N. Hollister, Superintendent of the National Zoological Park, Washington, D. C., of a published account of parturition in Macropus rufus, the deer kangaroo. The article in question is in the nature of a communication by the observer, Mr. A. Goerling, to the 'Western Mail,' of Perth, Australia, and was published January 3, 1913. Doctor Hollister's kindness in having the article copied makes it possible to present this interesting account to the readers of The Anatomical Record and thus render it more generally available to zoologists. The accounts of the birth of Didelphys virginiana, as detailed above, and of Macropus rufus, as reported by Mr. Goerling, are seen to be in perfect agreement on the one essential point, namely, that the young reach the pouch and find the teat by their own efforts and entirely without the assistance of the mother. It would seem, therefore, that this will be found to hold universally among the numerous species of the Marsupialia. The following are Mr. Goerling's notes dated December 19, 1912:

THE BIRTH OF THE KANGAROO[3]

The question of how the young kangaroo comes into the pouch has long been looked upon as answered. According to observations made, the young is born and placed on the pap by its mother, and this view has been accepted by zoologists.

On the 25th of February, 1906, I had the good fortune to make the most interesting and astounding observation. I had a number of Macropus rufus and M. cervinus in my possession, caged in various-sized cages. On the morning of the above mentioned date I was attracted by the peculiar behavior of a female M. rufus. She refused the feed placed before her; and on seeing blood marks in the cage, I

[3] The italics are mine.

came to the conclusion that the animal had just given birth to a young one. *She was sitting* in that resting position in which kangaroos can often be seen. The tail passed forward through the legs, thus she was sitting almost entirely on the thick part of her tail. She took no notice of my presence, although not more than three weeks in captivity, and *was busy licking and cleaning herself.* Presently she lifted her head, when I was astonished to see a young kangaroo clinging to the long fur about four inches below the opening of the pouch.

It moved about slowly, very slowly, through the fur upwards, using the arms in its progress, and *continually moving the head from side to side*, thus assisting the upward movement. Nearly 30 minutes were required by the little wanderer to reach the top of the pouch, the last end in a semicircle. During the whole of this time the mother paid no attention to her offspring, *offering no assistance, and leaving it entirely to its own exertions.* She then became restless; and not wishing to disturb her, I moved a short distance away, when she at once started to feed. A little later I paid another visit to her cage. She was sitting upright, the young one had disappeared, but the fur was still bearing evidence of the struggle, a plain visible track leading to and ending on the top of the pouch.

Now I had the explanation of a previous observation, but which I misconstrued at the time. I had a female Macropus woodwardi—Woodward's kangaroo—in captivity; and noticing blood stains in the cage, I believed the animal was hurt. I then noticed just such a young kangaroo clinging to the fur below the pouch, and thought the mother by restless movements had dislodged it.

My observation of the 25th of February, 1906, proves that *the new born kangaroo has to look after its own safety* and reach the pouch *without the mother's assistance.*

The arms of the new born kangaroo are strongly developed, the small hands open and close like a cat's paw, and by these strong little arms and hands the young one is enabled to labour its way to the pouch, the place of safety and nourishment.

The question now presents itself, how can the young, with such a hard and firmly closed mouth, attach itself to the pap? I am convinced that at the time of birth the mouth has a wider opening and is perhaps more elastic than such specimens possess which are found in the pouch of the mother. Once a young kangaroo is removed from the pap, it is unable to reattach itself.

As concluding proof that all newly born marsupials must reach the pouch by their own exertions, I mention that bandicoots, native cats and those very smallest of marsupials, the pouched mice, have the opening of the pouch in a reversed position to the kangaroos and phalangers. I had once in my possession a very small specimen of pouched mouse, having ten young ones in the pouch, each one not bigger than a grain of wheat. Only through the opening of the pouch being reversed are these smallest of born mammals enabled to reach it with safety and without much exertion.

Resumen por el autor, Frank Charles Mann.
Clinica Mayo, Rochester, Minnesota.

Páncreas accesorio.

En el presente trabajo se describen dos páncreas accesorios hallados en perros. En uno de los casos la glándula aberrante estaba situada a corta distancia distal del ligamento de Treitz, en la inserción mesentérica del yeyuno. La glándula presentaba forma triangular, midiendo 27 × 20 × 15 mm. Poseía un conducto definido que desembocaba en el yeyuno. Su estructura histológica corresponde a la del tejido pancreático normal, pero existe una cantidad relativamente pequeña de tejido insular, y los islotes son muy pequeños.

La segunda glándula aberrante estaba situada en la pared del duodeno, a corta distancia de la entrada del conducto pancreático menor. Presentaba forma de disco y medía 5 × 3 mm. Su estructura histológica revela la presencia de acini y conductos normales, pero hay una ausencia casi completa de tejido insular. En este último caso es interesante la estrecha relación entre el tejido pancreático y la musculatura lisa de la pared duodenal.

ACCESSORY PANCREAS IN THE DOG

F. C. MANN

Assistant Professor of Experimental Surgery and Pathology, Mayo Foundation (Graduate School, University of Minnesota), Rochester, Minnesota

FIVE FIGURES

Many cases of an accessory pancreas in man have been reported. At various times the separate reports have been collected (Opie, Ruediger, Warthin, Wiedman). An accessory pancreas has been found in the wall of the stomach, duodenum, jejunum, and ileum; in a diverticulum of the stomach, jejunum, and ileum; in Meckel's diverticulum, umbilical fistula, mesenteric fat, great omentum, hilum of the spleen, and capsule of the spleen. In some cases the accessory glands have been considered significant clinically in relation to atresia of some portion of the gastro-intestinal canal, obstruction, intussusception, pancreatitis, and malignancy.

From the embryologic standpoint the accessory pancreas has attracted considerable attention and study. The fact that the pancreas arises from two buds and the cells of origin are somewhat scattered seems at least partially to explain the development of accessory pancreatic tissue.

There are few reports of an accessory pancreas in species other than man, although some species are believed normally to have separate pancreatic tissue in the wall of the stomach or duodenum, and the possibilities of its embryologic development in other species are certainly as great as those in man. No reports of an accessory pancreas in the dog were found in the literature.

During two experimental operations on dogs in our laboratory two aberrant pancreatic glands were found. The account of the finding and the description of the two glands follows:

Dog D 93 (experiment 249–19), an adult mongrel bull, weighing 11.7 kg., was being operated on April 30, 1919, by Doc-

tor McQuay for the purpose of developing the technic in some gastro-intestinal operations. While I was demonstrating a method of finding the first portion of the jejunum in the dog, I noted what appeared to be an accessory pancreas just below the ligament of Tritz. Since I was not aseptically prepared to operate at the time, the exact nature of the gland was not determined. The proposed gastro-enterostomy was abandoned, however, and the left ureter was sectioned and anastomosed and the gall bladder removed by Doctor McQuay. The animal quickly recovered from the operation and gained in weight.

July 8, 1919, I explored the animal for the purpose of definitely determining the presence of an aberrant gland (experiment 443–19). The tissue was found to be an undoubted accessory pancreas. Some measurements of the size and position of the gland were taken. At necropsy these were found to be approximately correct. One small lobule, 4 by 2 by 1 mm., of the accessory pancreas was removed and fixed in neutral formalin-Zenker. The major pancreas was examined and found to be normal; one small lobule of it was also removed. Microscopic examination of these specimens showed both to be normal pancreatic tissue.

The animal was kept under observation, as it was planned to study the carbohydrate tolerance and then gradually remove the major pancreas in order to determine whether or not the accessory gland would take care of the carbohydrate metabolism. The animal was pugnacious, and March 5, 1920, was killed in a fight.

The necropsy (107–20) was performed shortly after death. All tissues were well preserved. The site of the accessory pancreas was carefully examined. It was located 32 cm. from the pylorus, 11 cm. below the upper attachment of the ligament of Tritz and 5 cm. below its lower attachment. The gland was roughly triangular, with the small side of the triangle attached quite firmly to the jejunum. It measured 27 mm. along the greater side of the triangle, 20 mm. along the opposite side, and 15 mm. across the small side attached to the jejunum. It was 6 mm. thick. It appeared to be composed of perfectly normal pancreatic tis-

sue. A small duct, extending from the middle of the side attached to the jejunum, passed through the jejunal wall. This duct measured 2 mm. in diameter and 5 mm. in length. On the jejunal side the duct emptied into the lumen of the intestine through a small opening.

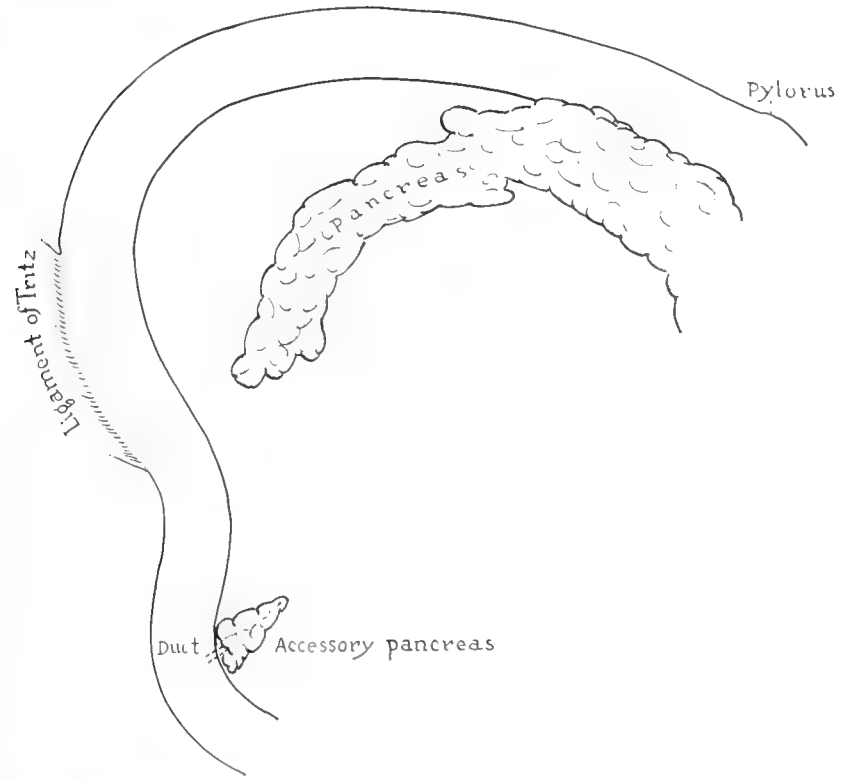

Fig. 1 Diagram showing the relative position of the accessory pancreas of dog D 93.

The major pancreas was large, weighing 45 gm. The animal was found to be normal except for a small lymphoma in the spleen, measuring 6 mm. in diameter.

Microscopic examination of many sections of the accessory pancreas showed it to be composed of normal pancreatic tissue. The acini appeared perfectly normal. A large number of islands

were scattered throughout the gland; it was noticed, however, that the islands were very small. In most instances not more than a dozen island cells were found in one group in a section. In comparison with the islands of the major pancreas they appeared very small indeed. Other than this decrease in island tissue and particularly in the size of the islands, no difference

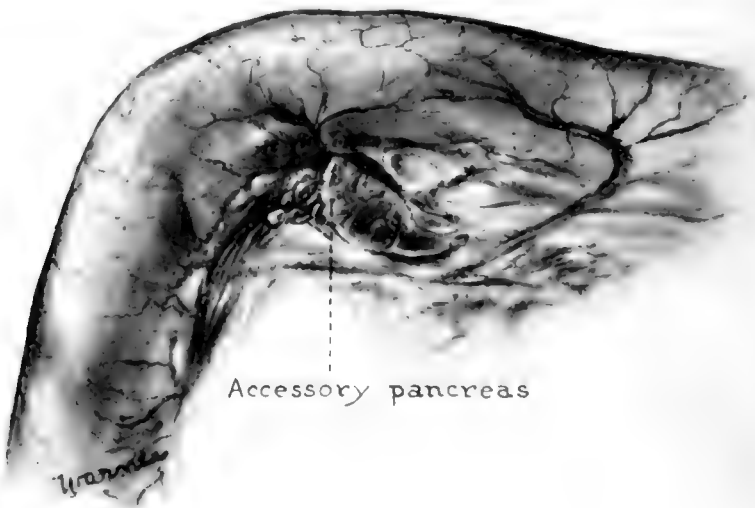

Fig. 2 Drawing of the accessory pancreas in its relation to the jejunum and the mesentery in dog D 93.

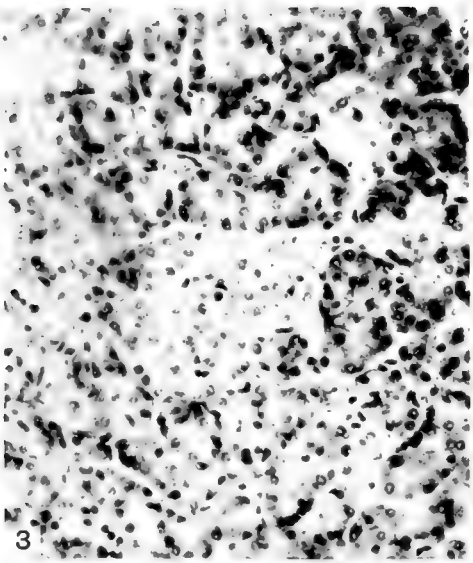
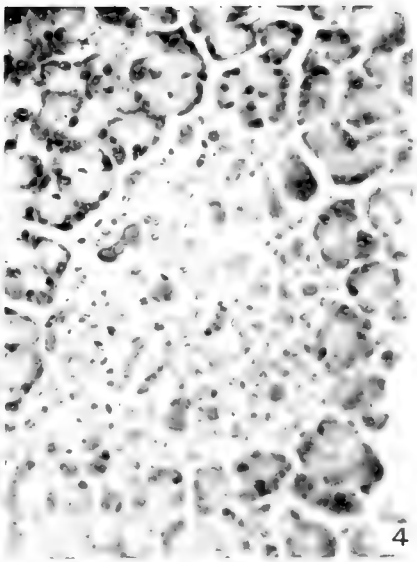
was noted between the major pancreas and the accessory gland (figs. 1 to 4).

Dog D 563 (experiment 200 20), a mongrel black and white hound, weighing 20.4 kg., was operated on March 26, 1920, for the purpose of making an Eck fistula. On pulling up the duodenum an accessory pancreas was found 6 cm. from the pylorus on the right side of the duodenal wall, and 3 mm. above the entrance of the minor pancreatic duct into the duodenal wall, making it about 0.5 cm. from the mesenteric border on the right side. The accessory gland was disk-shaped, 5 mm. in diameter,





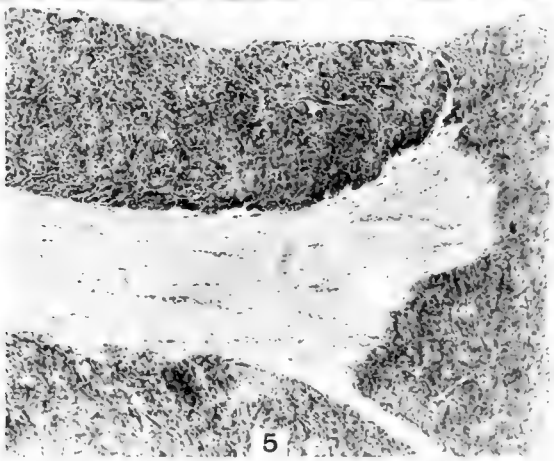


Fig. 3 Photomicrograph of the largest island found after a search through many sections of the accessory pancreas of dog D 93. It is normal, but small. ×250.

Fig. 4 Photomicrograph of one of the average-sized islands of the major pancreas of dog D 93. Compare with figure 3. ×250.

Fig. 5 Photomicrograph of section of accessory pancreas of dog D 563. Note the absence of island tissue and the intimate relation of pancreatic and smooth muscle tissue. ×75.

and 3 mm. thick. It was covered completely with serosa and imbedded in the muscularis, but was quite easily dissected out. It was impossible to determine grossly whether or not a duct connected it with the duodenum. The tissue appeared to be perfectly normal. A specimen was excised and fixed in formalin, and a specimen taken from the major pancreas just below the accessory gland was also fixed in formalin.

On microscopic examination the major pancreas was found to be normal, and several sections of the accessory gland showed this also to be normal pancreatic tissue. Very little island tissue was found. Scattered in various parts of the section were groups of a few, seldom more than six, of what appeared to be island cells. The gland had well-developed ducts; undoubtedly a duct connected it with the lumen of the intestine. The pancreatic tissue and smooth muscle tissue were intimately associated; prolongations of one dipped, finger-like, into the other (fig. 5).

Resumen por el autor, H. L. Wieman.
Universidad de Cincinnati.

Observaciones relativas al desarrollo temprano de la glándula suprarrenal humana.

Embrión de 9 mm. 1. Las crestas suprarrenales se extienden posteriormente desde las membranas pleuroperitoneales hasta las crestas genitales. 2. El único indicio de vascularización del tejido suprarrenal está representado por algun corte transverso de un capilar. 3. En la región suprarrenal los ramos comunicantes se extienden ventralmente mas allá de los ganglios prevertebrales del simpático, en forma de fibras nerviosas en apariencia desprovistas de células nerviosas. 4. Las células germinales extraregionales se presentan diseminadas en las proximidades de las crestas genitales.

Embrión de 12 mm. Las glándulas suprarrenales están claramente separadas de los tejidos que las rodean. 2. La región central de la glándula es una red muy vascularizada, cuyos vasos sanguíneos poseen paredes endoteliales bien distintas. 3. El lado medio de cada glándula está en íntimo contacto con la prolongación ventral del ramo comunicante y masas de células ganglionares. Algunas de estas aparecen entre las fibras de la porción distal del ramo, a lo largo del cual parecen emigrar desde los plexos celiacos y viscerales.

OBSERVATIONS IN CONNECTION WITH THE EARLY DEVELOPMENT OF THE HUMAN SUPRARENAL GLAND

H. L. WIEMAN

Zoological Laboratory, University of Cincinnati

TWO PLATES (NINE FIGURES)

The purpose of this contribution is to call attention to certain details in connection with the development of the human suprarenal gland, because they happen to be clearly illustrated in the material at hand. This material consists of two human embryos, nos. 1 and 4 of the author's collection, which were obtained some years ago, freshly killed and fixed, from Drs. H. L. Woodward and Charles Goosmann, of Cincinnati. No. 1 had been killed in a bichromate-acetic mixture, and no. 4 in Bouin's solution. The former measured 9 mm., crown-breech, and the latter 12 mm. Both measurements were made in 85 per cent alcohol after fixation, so that the sizes of the living embryos were somewhat larger than these figures. The embryos were embedded in paraffin, cut into serial sections of 10 μ thickness, and stained on the slide with Delafield haematoxylin and orange G according to the method of Morris ('09). Mitotic figures abound in both embryos, but the fixation is somewhat better in no. 1.

OBSERVATIONS

Embryo no. 1, 9 mm. The suprarenal glands are not recognizable as distinct organs, but consist of a thickening in the mesenchyme on either side of the root of the mesentery, forming a pair of broad ridges projecting into the body cavity from the dorsal body wall. Anteriorly these suprarenal ridges are continuous with the dorsal portions of the pleuroperitoneal membranes, while posteriorly they blend with the genital ridges. Laterally

each is separated from the mesonephros by a distinct groove (fig. 1). Occasionally a transverse section of a blood capillary can be seen in the center of each ridge, the beginning no doubt of the central vein of the adult organ.

The ridges are made up of mesenchyme which shows no evidence of differentiation. The ramus communicans divides into two at the level of the sympathetic ganglion where one of the branches terminates, the other passing ventralward into the mesenchyme. The cells composing the sympathetic ganglia stain more deeply than the surrounding cells, but beyond this they show no appreciable differentiation. The ganglia lie on either side of the aorta somewhat dorsal to it. The nerve strands (axis cylinders?) are easily distinguished and followed, owing to the fact that they stain readily with orange G. The ventral branch of the ramus communicans, which is really the direct ventral continuation of the latter, loses itself in the mesenchyme of the suprarenal region. It seems to be unaccompanied by nerve cells (fig. 3). From the picture one gets the impression that the nerve fibers are pushing their way through the mesenchyme, blazing, as it were, a track along which the ganglion cells are to follow later.

In the posterior part of the suprarenal ridge, the genital ridge, the subepithelial region of the mesonephros, and in the mesentery, one finds large cells with clear cytoplasm and standing out distinctly from all cells (fig. 3, 4, 5). These I take to be germ cells (primary genital cells). Their wide extraregional distribution indicates that these cells undergo a rather extensive migration before reaching the germinal epithelium. This of course is in keeping with what is known about the early development of germ cells in other vertebrates.

Embryo no. 4, 12 mm. The suprarenal glands in this specimen are distinctly marked off from the surrounding tissues (fig. 2). Each one lies with its dorsal surface against the pleuroperitoneal cushion, while in close contact with its median side are bundles of nerve fibers and ganglionic clumps. Near the ventral border, as shown in figure 2, some nervous tissue is pushed into the substance of the gland, but only to a very slight extent, definite

immigration, according to other authors, not taking place until a much later period.

The prevertebral sympathetic ganglion is now a very distinct mass of cells clearly differentiated from the mesenchyme. Its relation to the ramus communicans is somewhat different from that described for the 9-mm. embryo. There is no longer any evidence of a branching in the ramus communicans at the level of the ganglion, the latter lying more directly in the path of the ramus. The ventral extension of the ramus (fig. 1) now passes directly ventralward from the ganglion (fig 2, *v.r.*). Among the nerve fibers of the ventral extension of the ramus can be seen two kinds of cells: 1) those distinguished by a long narrow outline with nucleus of the same shape, which are probably sheath cells and, 2) large irregular cells with yellowish cytoplasm drawn out into processes and possessing rounded nuclei. The latter are undoubtedly migrating nerve cells (fig. 7). They are larger and differ otherwise in their appearance from the nerve cells found in the prevertebral ganglia (fig. 6), but are practically identical with the large nerve cells partially embedded in the ventral border of the suprarenal gland (figs. 2, 8). Comparing the pictures presented by figures 1 and 2 it would seem that in the latter stage the nerve cells are in the actual process of migrating ventralward along the paths marked out by the nerve fibers, which alone are present in the former stage. If some of these migrating nerve cells are destined to enter the gland to form its chromaffin tissue and others to pass on to form the ganglia of the coeliac plexus, there is no way in the preparations at hand of distinguishing the two kinds. According to Soulié ('03), the penetration of the cortical portion of the suprarenal by the parasympathetic cells commences at the 19-mm. stage, which is of course considerably older than the one dealt with here.

The cells of the gland itself are arranged in the form of a branching network penetrated with blood-vessels, and resembling the zona reticularis of the adult organ. A distinct endothelium forms the walls of the capillaries (fig. 9). The only other indication of differentiation in the gland is the ingrowing of connective-tissue trabeculae at the periphery.

DISCUSSION

His, Jun. ('91), described a preliminary nerve-fiber framework laid out in the form of rami communicantes, along which the sympathetic cells wander to form the ganglia. Streeter (Keibel and Mall, v. 2, p. 149) states that in human embryos the migrating cells can be recognized in advance of the loose strands of the tip of the growing nerve which extend through the mesenchyme toward the aorta, and that by the time a well-defined nerve trunk is established, the sympathetic cells have already completed that part of their migration, and the cells then found on the nerve trunk are sheath cells only.

In the 9-mm. embryo under discussion the nerve fibers forming the ventral extension of the ramus communicans beyond the sympathetic ganglia (fig. 1) may have been preceded by a migration of ganglion cells through the mesenchyme, but my preparations do not show nerve cells either among the fibers or at their distal ends (fig. 3). On the other hand, in the 12-mm. embryo the cells found scattered along the course of the fibers are undoubtedly nerve cells rather than sheath cells. I am therefore inclined to believe that some at least of the ganglia migrate to their final location along paths formed of nerve fibers. The well-known work of Harrison ('06) which shows very conclusively that ganglion cells of amphibian larvae develop axis cylinders as outgrowths of the cell body, strengthens my conviction that the nerve fibers forming the pathway develop originally as outgrowths from cells located in the cord. Whether the nerve cells subsequently found among the nerve fibers come directly from the spinal ganglia or from the prevertebral ganglia is another question. I can only say that the migrating nerve cells are larger and differ in outline from those found in the prevertebral ganglia.

As has been noted above, Soulié ('03) states that the penetration of the parasympathetic cells into the cortical portion of the suprarenal gland commences at the 19-mm. stage. Zuckerkandl (Keibel and Mall, v. 2, p. 173) states that the elements of the migrating cell masses, which are entirely or for the most part chromaffin-forming cells, are sharply distinguished from the

neighboring cortical cells by their smallness and intense stain. In my preparations one cannot say with certainty whether such cells are present or not. Deeply staining cells occur bordering the nerve strands and the ganglionic masses, and these may represent the chromaffin cells, but if so they are sharply defined from the nerve cells and are more distinctly epithelial in character.

Zuckerkandl (Keibel and Mall, v. 2, p. 171) found that the suprarenal glands are already vascularized in a 9-mm. embryo, whereas in my specimen of this age the only indication of vascularization is the occasional appearance in the suprarenal ridges of a cross-section of a blood capillary, which simply means that my embryo is younger than his, though both are the same length. In the 12-mm. embryo of my collection delicate endothelial capillaries form a very rich vascular network involving practically all of the gland except the cortical region. The central vein is not visible.

Hoffmann (93) and others have shown that the primordial germ cells are distinct from the elements making up the germinal epithelium of the gonad and that they exist a long time before the appearance of the latter. More recently, Swift ('14) has traced the history of the primordial germ cells of the chick from their origin in a specialized region of the germ-wall entoderm just at the margin of the area pellucida. These cells are carried by their own movement and later by that of the blood to all parts of the embryo and vascular area until in embryos of twenty-six to twenty-nine somites they are found in the splanchnic mesoderm near the radix mesenterii. With the formation of the gonad they gradually pass to that organ. Fuss ('11) describes extra-regional germ cells in a human embryo aged four weeks. He finds them in the mesentery directly under the peritoneum, but not in the germinal epithelium. According to his description, they are large cells of rounded outline, with clear cytoplasm and distinct nucleus. The cells measure 19 to 20 μ in diameter and the nuclei 12.75 μ.

In my 9-mm. embryo, which is somewhat older than the one studied by Fuss, I have found cells resembling the one pictured

by Fuss in his figure and corresponding in every way to those described in his text, except that the measurements I have made are somewhat less than his. Likewise I find the distribution of these primitive germ cells to be somewhat wider than he found, and in my preparations some of the cells have approached very close to the germinal epithelium (fig. 4). The 12-mm. embryo did not prove favorable for the study of these cells, so that I have no data on the range of distribution at this later stage. My observations on the 9-mm. embryo corroborate the statements of Fuss, which indicates that the germ cells of man like those of other vertebrates are characterized by period of migration in the early part of their history.

SUMMARY

9-mm. embryo

1. The suprarenal ridges extend from the pleuroperitoneal membranes posteriorly to the genital ridges.
2. The only indication of vascularization in the suprarenal tissue consists in an occasional cross-section of a capillary.
3. In the suprarenal region the rami communicantes extend ventrally beyond the prevertebral sympathetic ganglia as nerve fibers apparently free of nerve cells.
4. Extraregional germ cells are found widely scattered in the neighborhood of the genital ridges.

12-mm. embryo

1. The suprarenal glands are distinctly marked off from surrounding tissues.
2. The central region of the gland is in the form of a network, and is highly vascular, the blood-vessels having distinct endothelial walls.
3. The median side of each gland is in close contact with the ventral prolongation of the ramus communicans and masses of ganglia cells. Some of the latter are found among the fibers of the distal part of the ramus along which they seem to be migrating to form the coeliac and visceral plexuses.

Resumen por los autores, George B. Wislocki y Tracy Jackson Putnam.
Escuela Médica Harvard, Boston.

Nota sobre la anatomía de las áreas postremáticas.

Las areas postremáticas son masas de tejido situadas en el extremo caudal del cuarto ventrículo: están compuestas de células de neuroglia y están muy vascularizadas. Al fusionarse forman el techo del canal central de la médula. Están cubiertas de delicadas células ependimarias aplanadas, que difieren del epitelio que tapiza interiormente el resto del cuarto ventrículo.

En las áreas postremáticas del hombre se han hallado células nerviosas, designadas con el nombre de núcleos postremáticos. En los animales no se han encontrado células nerviosas en estas regiones. La rica vascularización de estas áreas es un hecho descrito repetidas veces. Los vasos provienen de las ramas piramidales de las arterias cerebelosas inferiores. No se sabe nada acerca de la significación funcional de estas estructuras. Las áreas postremáticas se tiñen intensamente con los colorantes vitales, y este hecho es sorprendente si se tiene en cuenta que todas las demás partes del sistema nervioso central, con excepción de la hipófisis, no se tiñen vitalmente. La coloración de las áreas puede explicarse por la acumulación de moléculas del colorante en las células del tejido conjuntivo situadas en las vainas de los vasos sanguíneos.

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED
BY THE BIBLIOGRAPHIC SERVICE, SEPTEMBER 13

NOTE ON THE ANATOMY OF THE AREAE POSTREMAE

GEORGE B. WISLOCKI AND TRACY JACKSON PUTNAM
Laboratory of Surgical Research, Harvard Medical School

The earliest investigators of the behavior of the benzidine group of vital dyes were impressed by the fact that the normal central nervous system remained unaffected by these substances. The choroid plexuses alone were deeply stained, and it was thought that they were responsible for the failure of the dye to enter the cerebrospinal fluid. The only portion of the brain which was observed to stain grossly, aside from the choroid plexuses, was the hypophysis. The dye appeared in this organ principally in the pars anterior.

On examining the tissue of the brain under the microscope, it was discovered, however, that it is not absolutely devoid of stain, since granules of dye-stuff were occasionally discovered in connective-tissue cells of the meninges, in the adventitial sheaths of the cerebral vessels, and in the capsule cells of the spinal ganglia. In the true nerve elements vital-dye granules were never observed under normal conditions.

On examining the brains of a variety of animals after repeated injections of trypan blue we noticed in the gross two bilateral areas at the caudal end of the lateral walls of the fourth ventricle which were quite as deeply stained as the adjacent choroid plexus. These areas were found vitally stained in several monkeys besides in a series of dogs, cats, and rabbits, so that there remained no doubt as to the constancy of the phenomenon (figs. 1, 2, and 3). No mention has been made of the behavior of these areas by either Goldman (1, 2, 3) or MacCurdy (4), to whom we are indebted for our knowledge concerning the distribution of vital dyes in the central nervous system. A possible reason why this staining may have been overlooked by Goldmann is that he worked upon mice and rats in which the areas would necessarily be very

minute. In the species of large animals studied by us the areas could hardly fail to attract attention. An investigation of the anatomy of the caudal end of the fourth ventricle showed these spots to be the areae postremae.

The lower end of the calamus scriptorius is only briefly described in most text-books of neurology, but it has been the object of special study in the human brain by several investigators, particularly Blake (5), Wilson (6), and Streeter (7).

The areae or eminentiae postremae, so named by Retzius, are paired mounds of loose, vascular tissue which overlie the caudal third of the nucleus vagi and protrude into the lumen of the fourth ventricle. At their superior extremities the areas lie just ventral to the line of attachment of the choroid tela. Caudally they converge and eventually fuse in the midline to form the roof of the central canal. A tiny pocket, the suprapostremal recess, exists, as Blake has observed in many animals, between the roof of the central canal and the roof of the ventricle or the obex.

Wilson (6) has described and pictured the variations which occur not infrequently in this region in the human brain. In some specimens he noted that the areae postremae fuse to form the roof of the central canal. In these instances a suprapostremal recess is formed, as in animals, between the areae postremae and the obex above. In other specimens, however, the areas fail to coalesce in the midline, and consequently the obex forms the dorsal wall of the central canal at its emergence into the ventricle. In the latter cases the eminentiae postremae are seen in section as bulgings in the lateral walls of the mouth of the canal.

In serial sections the minuter relationships of the areas may be observed. Near their upper poles they appear as low elevations projecting into the rhomboid fossa, bounded mesially and below by the alae cinereae and extending laterally to the line of origin of the taenia. Midway between their poles, in the region of their greatest development, they appear as two prominent masses bulging into the lumen of the ventricle and overlying the dorsal nuclei of the vagus nerves. A band of dense neurogliar tissue, the so-called funiculus separans of Retzius, is conspicuous in

this region. It separates the areae postremae from the alae cinereae which lie beneath and mesial to them. In sections taken farther back, it may be observed how the areae postremae gradually converge and finally fuse, enclosing a space between them and the ventricular floor, the orifice of the central canal. The entire surface of the areae postremae is covered by a delicate, flattened epithelium, and differs in this respect from the rest of the ventricle which is covered by cuboidal or columnar ependyma. The tissue of which the eminentia postrema is composed, consists of a loose network of neuroglia through which runs a rich plexus of arterioles and capillaries. The arterioles are surrounded by perivascular sheaths composed of connective-tissue cells. In addition to the vessels, fibroblasts, and neuroglia cells which were observed by Streeter (7) and Blake (5), the presence of neurones has been described in human material by Wilson (6). He suggests that these nerve cells be designated the 'nucleus postremus.' He also states that Stilling used the term 'Accessoriuskern' to designate the area postrema, and that the latter observer may therefore have been aware of the presence of nerve cells in that region We have confirmed Wilson's observation in several human brains, but have been unable to find nerve cells in preparations from any of the animals which we have examined.

The embryology of the area postrema has occasioned some discussion. Blake, who is apparently the first writer to investigate the subject, believes that it is part of the remains of the secondary rhomboid lip of His, in common with the obex and the ligula. As we have seen, however, the eminentia postrema is quite distinct from both these structures, which Blake's own illustrations also show. In his figure 28, the area postrema, marked 'secondary rhomboid lip,' is some distance mesial to the attachment of the velum. Elsewhere in the same paper, Blake speaks of the primary rhomboid lip as fusing to "produce a bridge of nervous matter over the emergence of the myelocoele into the fourth ventricle," which is doubtless the interpostremal fusion in this region. Wilson's conception seems much more tenable. He considers the area postrema as a part of the alar lamina of His.

We have studied two human embryos from the Harvard Embryological Collection. In the younger of these, a specimen of 40 mm., the area postrema could barely be made out as a spot of loose, undifferentiated neuroglia tissue, covered with flat ependyma, at the point of emergence of the central canal into the ventricle. In the other, an embryo of 78 mm., the eminentia postrema was perfectly distinct, and displayed all the characteristics of form and structure which mark the adult area, even containing a few nerve cells. In both specimens, the area was at a considerable distance from the roof of the ventricle. In the older one the heaped-up epithelium of the rhomboid lip was to be seen, entirely distinct from the flattened ependyma of the area postrema mesial to it.

The vascularity of the eminentia postrema has attracted the attention of all observers. Haller (8), in his paper on the comparative anatomy of the rhomboid fossa has described its vascular connections. It is supplied from the pyramidal branch of the inferior cerebellar artery (first described by Duret) by three or four long, slender, anastomosing trunks. The principal arteries run along the outer border of the area, and send many arching arterioles transversely across it, from which a plexus of capillaries drains into a set of venules along its mesial edge. The vessels of the eminentia postrema have no connection with those supplying the choroid plexuses and the velum. The blood supply of the areae postremae in the dog's brain is illustrated in figure 4.

We have sectioned the calamus region in a number of vitally stained animals (one monkey, two dogs, two cats, and a rabbit in serial sections) and have examined the areae postremae. Trypan blue was the vital dye employed. Its distribution was alike in all the species. It was observed to occur abundantly as blue granules in many of the connective-tissue cells of the 'adventitial cell' type which invest the small arterioles and capillaries of these richly vascular areas. Particles of dye were rarely observed in the endothelium of the vessels. None was found in the neuroglia cells or in the nerve elements of the adjacent ala cinerea. It is interesting that these areas are the only intrinsic part of the central nervous system which possesses sufficient mesodermal tissue to stain deeply with vital dyes.

Repetition of some of Weed's (9) experiments, in which a solution of potassium ferrocyanide and iron-ammonium citrate was introduced into the ventricles, failed to demonstrate any absorption in the region of the areae postremae.

The abundant blood supply of the areas, the behavior of trypan blue toward them, and the fact that they are covered by an extremely low ependyma raises the suspicion that the areae postremae have some function in the transmission of fluid from the blood stream into the cerebrospinal fluid. The further elucidation of this point would be extremely interesting.

Resumen por el autor, Alexander Petrunkevitch.
Universidad Yale, New Haven.

La unificación de la microfotografía.

La microfotografía puede simplificarse y al mismo tiempo hacer la mas científica por un proceso de unificación de los aparatos Para obtener este fin todas las partes del aparato microfotográfico deben disponerse de un modo especial. Después de esto deben prepararse tres tablas de datos, conforme se indica en el texto, una de ellas para los aumentos, la otra para los factores de exposición y una tercera para los factores relacionados con los filtros de rayos luminosos.

El uso de estos cuadros abrevia el tiempo de trabajo y la pérdida de material, eliminando todos los errores fluctuantes y dándoles valores permanentes. De este modo se aumenta considerablemente la eficacia del aparato. Las mejores combinaciones de placas y filtros para rayos han sido determinadas mediante pruebas y se describen para un cierto número de coloraciones sencillas y dobles de uso común.

STANDARDIZED MICROPHOTOGRAPHY

ALEXANDER PETRUNKEVITCH
Sheffield Scientific School of Yale University

ADVANTAGES OF STANDARDIZATION

While the trend of the manufacturer has always been to introduce as much standardization as possible into his methods of production, the scientific investigator has held strangely aloof from anything that might restrict the freedom of his individual effort. The reason for this lies in a partial misconception of the principle of efficiency as applied to science. The feeling of aversion for any standardization has been carried so far that freedom in the selection of methods and the consequent desire to avoid any limitation in the use of apparatus are causing the loss of more time than one would like to admit. None would nowadays expect a photographer to make his own plates or paper. Sensitizing plates to various rays or increasing their rapidity in the laboratory would be futile, for one can obtain on the market the desired product. At the same time the majority of microphotographic apparatus are made on the principle of a universal tool, to be used as it may please the photographer at the time, who sets up or dismounts the apparatus on every occasion when he works with it. The intensity of the light may be increased or diminished by an almost endless combination of adjustments in several parts, such as the source of light, the substage, the diaphragms, the rayfilters; the desired magnification may be obtained by the use of the one or the other combination of oculars and objectives; objects may be photographed with the camera in an upright or a horizontal position, etc. What is the result? Not only a tremendous loss of time due to constant rearrangement of the apparatus and to measuring of the magnification, but an unavoidable variation in the quality of the negatives

and an utter impossibility of duplicating negatives or of obtaining identical magnification after the lapse of a few days or even hours, if the apparatus has meanwhile been deranged.

The latter statement may seem like an unwarranted assertion to anyone who has not had sufficient experience in photographic measurement. Yet, unfortunately, it is quite true. In figuring the magnification, especially when it comes to higher powers, it is practically impossible to determine with absolute accuracy when the scale is focused, and the possible error is quite sufficient to make an appreciable difference in size. It means simply this, that within given limits there is always an error in the stated magnification and that this error cannot be overcome by practical means. But in standardizing the individual apparatus as will be explained below, we can fix the error so that it always will remain the same. If we were to make photographs of a long series of sections we would have at least the same magnification in every case, while under other circumstances the error itself would present a variable.

To be practical, the methods of standardization not only have to accomplish their purpose, but must be simple. Some books give long formulas, the application of which is troublesome and does not give reliable results. A certain amount of derangement in the apparatus will always be unavoidable. If we are to use complicated mathematical calculations every time we want to obtain a given magnification, we defeat our own purpose. From the point of view of theory, the methods of standardization applied by me may appear perfunctory; from the point of view of results obtained, they leave nothing to be desired. They do not remove the errors themselves, but the sources of errors, by making errors constant. And they allow of very rapid work of high quality. At the Osborn Zoological Laboratory where I have worked out the method of standardization and used the apparatus for considerable time, we are able to make a fine negative of any microscopic slide stained by one of the forty-odd stains commonly in use here and at any of the thirty-five different magnifications ranging from 12 to 3000 diameters, without making any calculations or measurements whatsoever except a simple multiplication

of two factors given in special tables. We are able to turn out a finished negative in less time than it would take to find the necessary extension of the bellows for the desired magnification and we can change from one given magnification to another in a few moments. Should the apparatus for some reason have to be temporarily dismantled, it can be again reset, although this of course would take considerable time. The maximum of efficiency is attainable only through fixation of parts.

CHOICE AND ARRANGEMENT OF APPARATUS

Not every microphotographic apparatus is suited for standardization. There are several essentials without which standardization becomes impossible. These are: a rigid bed consisting of one unit; a source of light of permanent intensity; graduated scales for all mobile parts; a set of rayfilters of permanent colors and known wave-lengths. An examination of the majority of microphotographic cameras made by the leading manufacturing concerns of all countries has shown that very few, indeed, may serve the purpose. Thus the largest cameras made by both Zeiss and Leitz in Germany are as if intentionally constructed in such manner as to preclude standardization. Of the British cameras, that made by Baker comes up to the requirements; while in this country the same may be said of the large horizontal camera manufactured by the Bausch & Lomb Company, that model which does not allow the raising of the bellows into a vertical position. As described in their catalogue, the camera has one very important defect which, however, the manufacturers remedy on request, and this is a single holder for rayfilters instead of two, as is imperative whenever one has to use monochromatic light of highly limited wave-length. With this correction and with additional scales engraved on parts of which I shall speak below, the camera proved to be quite suitable for the purpose in question.

A few words about the microscope may be in place here. The stand must be of a regular microphotographic model. From a practical point of view, the choice of lenses at present is largely

a matter of taste. We use Apochromats 16.0, 8.0, 4.0 and oil immersion 2.0. The best oculars to be used are so-called projection-oculars 2 and 4 as manufactured by Zeiss, since they give a flatter field. For small magnifications the micro-tessars are best. When they are used in place of an objective, the substage has to be removed. If possible, the microscope should be with sliding objective changers instead of a revolving nosepiece. These changers are made so as to allow the adjustment of the objectives to cofocal length. There have to be as many changers as there are lenses, and the lenses once screwed in and adjusted should not be again removed, as that would result in an appreciable change of magnification. For the same reason the stand must never be removed from the support to which it has been fastened, nor must the centering be deranged. This necessitates examining the microscope slide for the part to be photographed in a rather awkward position with a consequent loss of time. The difficulty may be overcome by a special construction allowing the replacement of the microscope in the identical position after its removal for the purpose of focusing. But in absence of such a contrivance, the removal of the stand is not permissible under any circumstances. Correct centering of the microscope requires a great deal of time, much more than the loss due to inconvenience in focusing. The support for the microscope is also movable along the bed, and when the microscope has been once centered it becomes necessary to record the exact division on the scale of the bed at which the support has been fastened. This gives a guaranty that in case the apparatus has been dismantled, it may again be assembled without any change in the values of the tables.

THE LIGHTING SYSTEM

Whatever the source of light and the system of condensing lenses, the intensity of light must remain the same for a given record. With other words, the lighting system must be of such a kind as to allow exact recording and returning to each given combination within the shortest time, without any measurements or calculations whatsoever and in the simplest manner possible.

This can be accomplished only if every movable part is provided with an arrow or a pointer and its position recorded on a corresponding immobile scale. If the source of light be a carbon arc, it is best to select once, by experimenting, the most satisfactory distance of the arc from the lens and mark the position of the carbon-holder by means of a transverse line scratched or engraved on the immobile bed of the holder. Still better, to make a ring of a flat strip of heavy copper and rivet it in such a position that the arc is in the correct position when the carbon-holder abuts against the copper ring. This precludes all mistake, is easily done, and requires nothing but the commonest tools. The arc light as furnished by the Bausch & Lomb Company, even under such circumstances, is not a permanent source of light, but the variation in intensity, if the arc is watched, is not sufficient to impair seriously the quality of the work.

All diaphragms must be graduated, for which purpose it is best to measure the diameter of the opening at full stop and engrave lines showing when the diaphragm is closed to one-half its diameter, to one-fourth its diameter and so on. The diaphrams of the microscope must also be graduated in the same manner.

It is absolutely indispensable that the position of the microscope substage should also be recorded. For this purpose the arm carrying the substage should be graduated. That position in which the substage is brought as far as possible toward the objective is most conveniently designated as the zero of the scale, and the scale itself may be metric or English or quite arbitrary, provided the divisions are well marked. Even, bright illumination is obtained by placing the substage condenser in the position which gives critical illumination, and which may be more or less easily found by racking the substage nearer toward or further away from the objective. What is desired in practice is the simultaneous focusing of as many structures of an object as possible. In a photomicrographic instrument provided with a complete condensing system, such as used in the Bausch & Lomb apparatus, this so-called 'depth of focus' is most easily increased by racking the substage away from the objective. The optimum position of the substage may be judged by an examination of the

image of a slide on the ground-glass. Any further increase in the distance of the substage will result in a decrease in light intensity and loss of definition. The optimum position of the substage is different for every objective. The lower the magnifying power of the objective, the greater will be the distance of the substage from the objective. Once the optimum position has been determined for every objective, it must be recorded.

HOW TO PREPARE A TABLE OF MAGNIFICATIONS

The first step in the preparation of a table of magnification is the choice of magnifications desired. If the oculars used are of the common compensation kind, the determination of magnifications is so simple that any number of magnifications may be recorded. All one has to do is to determine the position of the ground-glass carrier for two magnifications at the extreme ends of the bed, let us say for 100 and 500 diameters. The intermediate positions may be derived by a simple calculation, remembering that for a given optical system the magnification is in direct ratio to the extension of the bellows.

The use of projection oculars precludes, however, the application of such a simple method. These oculars are supplied with a correction scale which must be used if the oculars themselves are used at all. The 'raison d'etre' of such oculars is their greater flatness of the field which is obtainable only by the use of the correction scale. Zeiss furnishes a formula which may be used to find the necessary correction for a measured extension of the bellows. Unfortunately, there are two reasons why such a procedure is inapplicable in the case of a standardized instrument. First, it requires in every case the measurement of the extension of the bellows and, second, the magnification itself is changed by the adjustment of the correction scale. With other words, if we were to prepare a magnification scale by the method used for common or compensation oculars, we would find, on correcting the field of the projection ocular, that this has resulted in a change of the magnification and that to obtain the desired magnification we have to measure it instead of simply setting the bellows to a given scale. This means, therefore, that the preparation of a

magnification table for use with projection oculars is not a simple process of calculation and requires careful measurements.

It is most convenient, therefore, to select a list of magnifications which are most desirable and which will prove to be sufficient in the majority of cases. The next step is to find the proper position of the bellows for each magnification given, for each combination of objective and ocular. This can be done by the use of a stage micrometer, such as furnished by any reliable optical company, and an exact millimeter scale by means of which the image of the micrometer scale on the ground-glass may be measured. After the bellows have been extended to give approximately the desired magnification, the projection ocular is corrected by the turning of its graduated disc until the edge of the visible disc of light on the ground-glass is quite sharp. This position is recorded in the table. Next the carrier of the ground-glass is moved nearer or further away from the microscope until the millimeter scale shows that the desired magnification has been obtained. Of course, the micrometer scale must be in focus. The position of the ground-glass carrier on the bed may now be recorded. If it is difficult to decide when the micrometer scale is in focus, the process may be repeated several times and the mean of the observations used for the record. It is tedious work, but it pays in the end, because it need never to be repeated. In the table, corresponding with each magnification two figures should therefore be given, one showing the position of the correction disc in the projection ocular and the other the position of the ground-glass carrier on the bed. Such a table naturally has value only for the given combination of stand, objective, ocular, and bed, and would be of no use if reproduced here. Each manufacturer, however, following these instructions, could easily prepare and furnish such a table for a standard equipment.

In preparing the table of magnifications one must bear in mind that the objectives give best definition at a given length of the tube, usually 160 mm. The use of a revolving nosepiece requires the extension of the microscope tube to only 145 mm., because the nosepiece itself measures 15 mm. The use of slid-

ing changers requires an extension of only 140 mm., because the changers measure 20 mm. Should the extension become deranged during the work, the magnification value would also change. To prevent this in the most efficient way, a ring should be made from a strip of flat copper and placed permanently on the microscope tube. The width of the ring may be made of the correct size by filing it down until the tube is in its proper position when firmly moved against the ring. Once placed on the tube, the ring should be left there permanently.

In my table I have twelve vertical columns, each for a different combination of objective and ocular. The magnifications are given in a special column on the left of the table. Each vertical column has two subdivisions, one for the ocular correction, the other for the ground-glass carrier. The figures of each column interlap with the figures of the next column, because the same magnification may be obtained by the use of two or three different objectives and oculars with an increase in the length of the bellows, thus permitting a choice of the most suitable combination in each individual case. For example, if definition is most important, the immersion lens may be used with a lower ocular and shorter extension of the bellows. Where, on the other hand, depth of focus is more important than definition, the same magnification may be obtained by using an 8-mm. objective with a more powerful ocular and longer extension of the bellows. If for some reason, after having examined one combination, one is not satisfied with the result as shown in the image on the ground-glass, it takes but a few seconds to change the combination and to try out several other combinations for the same magnification. Imagine what labor it would entail if we had no table by which to go in such a case!

HOW TO PREPARE A TABLE OF EXPOSURE FACTORS

Only in very rare instances microphotographs can be made without the use of rayfilters. Since the object of a microphotograph, barring a few exceptions of which I shall speak later, is to show as much detail as can be obtained, it is absolutely neces-

sary to know the best combination of rayfilter and plate to be used in each individual case. It would be possible to prepare a single table from which one could find not only this combination, but the necessary exposure in seconds for each given magnification. But such a table would require so many vertical and horizontal columns, that it would defeat its own object of simplifying the procedure. It is quicker to find two factors, one in each of the two small and simple tables, and to compute the necessary exposure by a multiplication of these factors. This can be accomplished if one of the tables shows the exposure factors for all given magnifications without any rayfilter and the other shows the factors for all combinations of plates and rayfilters.

The relative speed shown for dry plates in various photographic manuals and exposure meters naturally refers only to exposures in daylight with a common photographic camera and a lens of a given aperture and focused on infinity. I have compared and controlled several of these tables, and having selected the most important brands of plates am giving here, for the convenience of the reader, a table showing the relative exposure factors or speed of such plates, assuming that the speed of the Standard Orthonon plate equals 1.

Relative exposure factors or speed of photographic plates in daylight without rayfilter

Regular plates

Cramer's Crown	1
Marion Record	$\frac{1}{4}$
Seed Graflex	$\frac{1}{4}$
Seed 27 gilt edge	$\frac{3}{4}$
Seed 30	$\frac{2}{5}$
Seed 26×	$\frac{3}{2}$
Seed 23	3
Stanley	1

Orthochromatic plates

Cramer's Instant Iso	1
Cramer's Mediu n Iso	2

Paget direct colour, with screen and rayfilter	24

As in the preparation of the magnification table, so in the preparation of the table of exposure factors for the given magnifications one cannot be guided by the simple rule that exposure stands in direct ratio to the square of magnification. This rule is of great help in preparing the table for a single system, where nothing but the ocular or the extension of the bellows is changed. But when it comes to the use of another objective, two new factors must be taken into account. It is well known that exposure varies as $\frac{1}{(N.A.)^2}$ of the objective, and this formula does not apply to oil-immersion objectives. Moreover, it is desirable to use the optimum position for the substage condenser and this position, as explained in the paragraph on the lighting system is a different one for every objective.

The best way to proceed is, therefore, to ascertain by actual exposure the time of correct exposure for a given magnification for each objective at the optimum position of the substage. Once these are obtained the correct exposures for all other magnifications for each system may be calculated. For example, if you have found that the correct exposure for an Orthonon plate at

100-diameter magnification obtained by the use of an objective apochromate 16 mm. in combination with a projection ocular 2 and optimum position of the substage condenser at mark 5 of your scale is 0.04 second, then the exposure for the same combination at 400-diameter magnification, even if that magnification has been obtained by the use of ocular 4, will be 0.64 second.

Unfortunately, it is by no means easy to decide what is a correct exposure. To ascertain it as nearly as possible it is imperative to use time and temperature development and fractional exposure. My experiments were made with the following developer which has many good qualities, does not stain the fingers or the plate, but must be used fresh in every experiment, since the time of development increases considerably with the use of the developer.

Pyro-acetone developer

Solution A

Water	500 cc.
Oxalic acid	1 gram
Pyrogallic acid	30 grams

Solution B

Water	1000 cc.
Sodium sulphite, dry	120 grams

For use take

Water	120 cc.
Solution A	15 cc.
Solution B	30 cc.
Acetone	6 cc.

If the mixture has a temperature of about 18.3 to 18.8°C. (65 to 66° F.), then the image of a correctly exposed plate will appear in fifteen seconds and the development will be completed in six minutes from the time the plate was immersed in the developer.

Fractional exposure consists in making four different exposures on the same plate in such a manner that each following exposure is twice as long as the preceding one. These exposures may be represented as a, 2a, 4a, 8a. To make such an exposure, the

slide of the plate-holder must be marked with three parallel lines dividing the plate in four quarters. The slide is opened and the plate is exposed *a* seconds (or fractions of a second). Now the slide is moved in one quarter and the plate is exposed again *a* seconds (or fractions of a second). When moved in two quarters the exposure should be 2a and when the plate-holder is moved in three quarters the exposure should be 4a.

The choice of an object to be photographed is also important. A stained section will not do and it is advisable to use a slide which will permit the use of both low- and high-power objectives. I have used the Diatome Arachnodiscus and a thin section of human bone. The time of the appearance of the four images in the developer will at once indicate which exposure is nearest to be the correct one. It is advisable to control the experiment by making another fractional exposure at a higher magnification.

The completed exposure table will consist of as many vertical columns as there are objectives in the outfit, and for each of these columns the optimum position of the substage must be indicated at the top of the columns. A special column on the left of the table will contain all magnifications as accepted in the magnification table.

HOW TO PREPARE A TABLE OF RAYFILTER-PLATE FACTORS

The choice of rayfilters is not entirely a matter of taste. While one can use fluids in special containers, it is simpler and better to buy a set of dry rayfilters from a reliable firm with stated regions of light transmitted. Such filters are more permanent and easier to use. It is not advisable to make dry rayfilters in the laboratory unless the laboratory is provided with instruments which permit the preparation of identical rayfilters at any time in case of inadvertent damage, since a variation in the region or in the intensity of light transmitted would affect the exposure. At the Osborn Zoological Laboratory we have accepted as a standard equipment for all photographic work Cramer's photomicrographic rayfilters. There are ten of them and singly or in combination they transmit the following regions:

1	A–6350	3+4	6920–5840
2	A–6100	3+7	5900–5800
3	A–5850	3+8	A–7000
4	A–5400	4+5	6870–5525
5	A–5250	4+7	5900–5660
6	A–5100	5+7	5900–5400
7	5800–5000	5+8	5530–5350
8	5200–3950	6+7	5900–5150
9	5200–3500	6+8	5350–5150
10	Visual luminosity	6+9	5600–5200
		7+8	5200–5000
		7+9	5300–5100

The Wratten 'M' filters transmit somewhat different regions, as shown in their booklet.

If all plates were equally sensitive to the same regions of the spectrum, the same factors would apply for all makes. But experience shows that one brand of plate may be twice as rapid as another in daylight yet be considerably slower with a special rayfilter. Thus the Standard Orthonon is twice as rapid as Cramer's Medium Iso in daylight, and four times as slow in green light in the region 5200–5000. When it comes to the use of red light, nothing but panchromatic plates can be used. The Wratten 'M' plate answers this purpose admirably, but for orange, yellow, and blue light the Orthonon plate is preferable if for no other reason than greater ease and safety in handling it. For green light we use Cramer's Iso Medium or Instantaneous Iso.

To find the correct rayfilter-plate factors it is necessary to use the same slides as were used in the preparation of the table of exposure factors without rayfilter. Fractional exposure with a rayfilter will easily show how much the normal exposure must be prolonged to obtain the same results. A separate exposure experiment must be made for every rayfilter or combinations of rayfilters and plate. Thus was the following table of RP factors obtained, but naturally it is good only for the Cramer rayfilters.

Table of R-P factors for use with Cramer's photomicrographic rayfilters and dry plates. The unit of comparison is the normal exposure for a standard Orthonon plate without rayfilter. The figures are good only when the light is an open arc

CRAMER'S RAYFILTER, SINGLE OR COMBINATION OF TWO	STANDARD ORTHONON PLATE	WRATTEN M PLATE	CRAMER'S MEDIUM 180 PLATE	CRAMER'S INSTANT 180 PLATE

Without rayfilter	1	1	2	1

THE CHOICE OF THE RAYFILTER COMBINATION

The choice of a rayfilter will naturally depend upon the results to be attained. At times it may be desirable to get as much contrast as possible regardless of the loss of detail, especially if some single structure should be shown clearly. In such cases a rayfilter which makes the structure appear black to the naked eye, i.e., a rayfilter which absorbs all rays transmitted by the structure to be photographed, is the one that will give the best results. If the section has a counterstain, if for example the stain employed was haematoxylin-eosin, and it is desired to show only the structures stained with haematoxylin, then an eosincolored rayfilter which will transmit all rays of that color may be used with advantage. In the majority of cases, however, the photograph will be much more satisfactory, if the contrast is less, but the detail greater. To find the right combination that will answer

this purpose is not an easy matter. One may be helped by an examination of each staining fluid through a direct vision spectroscope, but the final decision has to be derived from an actual exposure. It will be also found that an examination of the image on the screen with different rayfilters will be of great help. In case of doubt, two or three different combinations may be tried and the negatives compared. In the following table is given a list of the commonly employed stains and the best combinations of plate and rayfilter for each.

CORRECT EXPOSURE

The exposure factor multiplied by the R-P factor will give the correct exposure in seconds for the given combination of stain, rayfilter, objective, substage position, and magnification as indicated in the tables. If care is exercised not to overlook a single one of these conditions and to see to it that the source of light is also in its proper place, the only element unaccounted for remains the microscopic slide itself. The quality of the tissue, the intensity of the stain, the thickness of the section, play no inconsiderable part in the determination of the correct exposure. If the tables are prepared from a very thin and transparent section, the deviation in exposure of thick sections will be great. It is therefore advisable in standardizing the apparatus to use either medium thick sections, or else to take the mean of two figures obtained from an exposure of a very thin and a very thick section under identical conditions. No satisfactory rules can be formulated in regard to the transparency factor of the microscopic section, but the student will rapidly learn the necessary increase or reduction in the time of exposure.

As a rule, correct exposure gives the best results. Under circumstances, however, overexposure is desirable and even indispensable. Just as in a brilliantly sunlit room one obtains a much better picture of details if one gives long exposure and develops the plate with a restrainer, so in microphotography details may be brought out by overexposure when some parts of

a section are much more transparent than others. In overexposing a plate it is advisable in such cases to know the exact ratio of overexposure as the restrainer should be used in strict conformity with that ratio. The pyro-acetone developer of the formula given above lends itself admirably to such work. I have made a series of experiments in which the correct exposure was first carefully ascertained for a given microscopic slide, and the exposure then increased twice, four times, eight times, sixteen times, thirty-two times, sixty-four times, one hundred twenty-eight, and two hundred fifty-six times. Measured quantities of potassium bromide were added to the developer and fractional exposure used to see the results more clearly. The plates were left six minutes in the developer. A similar series of plates was left seven minutes and a third eight minutes. The best negatives were noted and a fresh plate was exposed same length of time and developed in the same manner as a control. Thus several formulae were obtained, each giving excellent results for the given overexposure. Those who have seen my negative which was overexposed about 130 to 150 times and then developed with the restrainer agree that aside from its yellowish color one would never guess that the plate was overexposed.

a. Pyro-acetone developer for plates overexposed 4 times:

Normal developer	Water	120 cc.
	Solution A	15 cc.
	Solution B	30 cc.
	Acetone	6 cc.
10 per cent potassium bromide		1 cc.

Develop 6 minutes at 65° F.

b. Pyro-acetone developer for plates overexposed 8 times:

Normal developer as above
10 per cent potassium bromide ..... 2 cc.
Develop 8 minutes at 65°F.

c. Pyro-acetone developer for plates overexposed 16 times:

Normal developer as above
10 per cent potassium bromide ..... 10 cc.
Develop 8 minutes at 65°F.

d. Pyro-acetone developer for plates overexposed 32 times:

Normal developer as above
10 per cent potassium bromide..... 20 cc.
Develop 8 minutes at 65°F.

e. Pyro-acetone developer for plates overexposed 130 to 150 times:

Normal developer as above
Potassium bromide (powder)..... 4 grams
Develop 8 minutes at 65°F.

Resumen por el autor, Frank Blair Hanson.
Universidad Washington, Saint Louis.

La historia de los estados más tempranos de la clavícula humana.

La literatura sobre la clavícula contiene tres teorías sobre el orígen de dicho hueso. Se ha considerado como un hueso puramente cartilaginoso, como un hueso puramente dérmico y como un elemento mixto, que contiene porciones cartilaginosas y dérmicas. Puesto que el último trabajo sobre este punto (1918) intenta resucitar la teoría expuesta en el primer trabajo sobre la clavícula (1864), el problema queda sin resolver, abierto a nuevas investigaciones.

El autor ha estudiado los estados mas tempranos del desarrollo de la clavícula humana en una extensa serie de embriones humanos del Laboratorio Carnegie de Embriología, confirmando la opinión que considera a la clavícula como un elemento que se osifica en sus primeros estados como un hueso puramente dérmico, al cual se agrega el cartílago en estados ulteriores, pero sin significación morfológica.

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED
BY THE BIBLIOGRAPHIC SERVICE, OCTOBER 4

THE HISTORY OF THE EARLIEST STAGES IN THE HUMAN CLAVICLE

FRANK BLAIR HANSON

Department of Zoology, Washington University, Saint Louis, Missouri

FOUR PLATES (THIRTEEN FIGURES)

INTRODUCTION

The clavicle is one of those elements of the human skeleton concerning which the last word has not yet been spoken.

Beginning with Gegenbaur in 1864, an enormous literature has arisen, the earliest of which would be now of historic interest only, were it not for the fact that the most recent paper on the clavicle (Huntington, '18) attempts to restore the old Gegenbaurian hypothesis of a cartilaginous precoracoidal core in the human clavicle, thus opening again an old controversy on the origin of the clavicle as a dermal or cartilage element.

The point of interest, then, in this present paper is whether the human clavicle originates in cartilage or as a dermal element or is derived in part from both cartilaginous and membranous elements.

Gegenbaur ('64) considers the clavicle in man to be a pure cartilage bone; Broom ('99) and Fawcett ('13) claim that the cartilage present has no morphological significance and that the clavicle is as purely a dermal bone as is the dentary; while Paterson ('02) and Fitzwilliams ('10) combine these two views, holding that the clavicle is of dual origin, its inner end being formed in cartilage and its outer as a dermal element.

This confusion in the literature of the clavicle is reflected in the text-books of human anatomy and puts new and uncalled-for difficulties in the by no means rosy pathway of the first-year medical student.

THEORIES OF CLAVICULAR ORIGIN

Gegenbaur ('64) thought that he had found the human clavicle developing in cartilage, and probably with the anuran shoulder-girdle in mind, claimed that the cartilage present was a remnant of the old precoracoid, thus determining the character of the clavicle as a cartilage bone. It is certainly true that in the frog the precoracoid does enter into and constitute the core of the clavicle, which is overlaid on the anterior side by a membranous element, and it is also true that in many of the mammals the clavicle contains a relatively large amount of cartilage at a fairly early stage. In man the cartilage is of a peculiar kind called by Mall a 'precartilaginous tissue' (figs. 4 to 6).

Gegenbaur has been supported in his view of a precoracoidal contribution to the clavicle by Huntington ('18), and in a private communication to the author concerning the matter Huntington states his position not only on the clavicular complex, but also on the entire shoulder-girdle as follows:

> this structure (shoulder-girdle) as a whole represents all the various possible combinations which result from the fact that it develops by the union of two originally distinct and separate elements, the exoskeletal and the primordial cartilaginous girdle, in different degrees in different types.
>
> As regards the clavicle the different proportional amounts of the dermal and cartilaginous contribution is well shown in the different vertebrate classes. The process of envelopment of the procoracoid by the clavicle is developed to a widely varying degree in individual Anure types, up to the complete replacement of the cartilage by an element originally dermal in origin.

In the above statement of Huntington's is a somewhat plausible explanation of the widely different views expressed as to the constitution and homology of the clavicle. Two distinct elements, exoskeletal and cartilaginous, have contributed to it unequally in different classes of vertebrates, and even in different genera of the same class. This is apparently the case in the Amphibia and Reptilia, where the cartilaginous and dermal elements vary from a nearly pure precoracoidal cartilage bone to a purely dermal bone such as that found in many of the reptiles.

The hypothesis of Gegenbaur and Huntington has much to recommend it at first sight and does seem to account for the variations met with in the clavicle of the different groups of vertebrates by the inclusion of a greater or lesser amount of the cartilaginous precoracoid into this element. Assuming that the coracoid process of man is the homologue of the metacoracoid or posterior coracoid of Permian reptiles and the precoracoid to be the cartilaginous part of the clavicle, a most direct and beautiful homology can be drawn between the shoulder-girdle complexes in the frog and man, for which comparison examine figures 1 to 3.

However, as Watson ('17) remarks, the anuran shoulder-girdle is of totally unknown ancestry, and the group as a whole being characterized by extraordinary specialization, any comparisons between the frog and other forms are very hazardous and should receive most careful checking and corroboration. And this is especially true in a comparison with the human shoulder-girdle so long as the homology of the coracoid process is still in doubt. Further on I shall attempt to show that the coracoid process is the homologue of the precoracoid rather than the metacoracoid, and, if this be true, the theory of Gegenbaur and Huntington is no longer tenable.

Broom ('99) was the first to cast doubt upon Gegenbaur's hypothesis. He claimed that, while cartilage was present in the clavicle, it did not appear until after ossification had begun in the dense connective tissue, and concluded therefore that the clavicle was a purely membrane bone. Broom examined a number of marsupials, reptiles, and other Tetrapoda, including man, and found that in all these ossification of the clavicle preceded the appearance of true cartilage cells.

Mall ('06) studied by the Schultze method of clearing, the ossification centers in an extensive series of human embryos less than 100 days old. He was the first to announce the dual origin of the clavicle from two distinct centers of ossification, a medial and a lateral. Mall did not, however, give an opinion on the significance of these two centers.

Fawcett ('13) examined a series of human embryos sectioned transversely and otherwise, and found in serial sections the two

centers of ossification Mall had seen in cleared specimens. Ossification began in the outer end of the inner half of the clavicle and in the inner end of the outer or acromial part of the clavicle. No cartilage cells were present until after the appearance of these two ossified centers. At this stage the inner and outer parts of the clavicle had no connection, but were separated by the investing perichondrium. In the 19-mm. stage (crown-rump measurement) a bony bridge develops and connects the two centers (figs. 6 to 9).

Another important point made by Fawcett is that the connection of the coracoid-clavicular ligament is always with the acromial half of the clavicle, and not, as Fitzwilliams ('10) thought, with its sternal end. In cases of cranio-cleido-dysostosis Fitzwilliams found a ligament connecting the inner part of the clavicle with the base of the coracoid process. He identified this as the coracoid-clavicular ligament and urged that it was in cases of this disease a prolongation of the coracoidal contribution to the sternal part of the clavicle. That Fitzwilliams is incorrect in his identification of this ligament is beyond all doubt, as is shown very clearly in figures 6 and 7. In all the specimens I have examined in the Mall Collection, the coracoid-clavicular ligament extends from the acromial half of the clavicle to the coracoid process, and Fawcett found the same thing in his material. Watson ('17) publishes a photomicrograph of a cross-section through the shoulder region of the marsupial Trichosurus, which shows that in this group also, as in the primates, the coracoid-clavicular ligament is attached to the acromial part of the clavicle.

It is admitted by all investigators that at a comparatively early stage cartilage does appear in the clavicle in considerable quantity and contributes to the ossification process. The question seems to hinge on the amount and character of the cartilage present and whether this has morphological significance such as is attributed to it by Gegenbaur, Huntington, Fitzwilliams, and Paterson or is merely a neomorph comparable to the cartilage in the mandible and other membrane bones (Broom, Fawcett, Watson).

Paterson has a number of papers on the shoulder-girdle and has briefly stated his views on the homology of the clavicle in his 1902 paper as follows: that the clavicle possibly contains more than one morphological unit (judged by its ossification, directly in the outer part, indirectly through cartilage in the inner part).

Fitzwilliams ('10) also maintains that there are two distinct elements involved in the origin of the clavicle, one is a dermal element and is confined to the outer half of the clavicle, while the other is cartilaginous and represents the precoracoid of the lower forms. His arguments for the dual origin of the clavicle are the most complete and strongest on that side of the question. They may be summed up as follows:

a. There are two centers of ossification present in the clavicle, and this may well indicate that the bone is a composite one and may be traced back to dissimilar elements in lower forms.

b. It is pointed out that the inner end of the element is a round bone, and here is found the greater amount of the cartilage present. Round bones are, in general, cartilage bones, and this argues in favor of the inner half of the clavicle being of cartilage origin. On the other hand, the outer half is flattened and has more the characteristics of the flat bones of the skull which are membrane bones. The first center of ossification also appears in the outer half and is well advanced before cartilage appears.

c. The disease known as cranio-cleido-dysostosis attacks membrane bones principally, and when present in the clavicle the outer part is usually the one affected, while the inner half remains normal. This again points to the inference that the outer half of the clavicle is of membranous origin, the inner half cartilaginous.

d. There is, after all, a rather large deposit of cartilage present in the developing clavicle, and as this cartilage enters into and becomes a part of the bony product, it may have had an ancestral history.

e. The above points are emphasized by the known conditions in the Anura, where the precoracoid becomes the cartilaginous core of the investing dermal tissue, the two elements quite clearly uniting to form the anuran clavicle.

f. The clavicle, therefore, according to this point of view, is the result of two interacting tissues, one a dermal element and the other cartilage, which contribute unequally in the different classes of vertebrates to this structure, so that investigators finding one or the other elements greatly in excess in the form immediately under observation were led to take such divergent views as above indicated.

The three theories of clavicular origin now in the literature are set forth with their respective sponsors in the following table:

	CARTILAGINOUS CLAVICLE	DERMAL CLAVICLE	MIXED CARTILAGINOUS AND DERMAL CLAVICLE
Broom ('99)		*	
Fawcett ('13)		*	
Fitzwilliams ('10)			*
Gegenbaur ('64)	*

Huntington ('18)			*
Paterson ('02)			*
Watson ('17)		*	

OBSERVATIONS

Recently I have had the privilege of examining the cleared specimens of human embryos upon which Mall ('06) based his paper on ossification centers, and also have studied the earliest stages of the clavicle in the splendid collection of serial sections of human embryos in the Carnegie Laboratory of Embryology at the Johns Hopkins Medical School.[1] My purpose was to determine, if possible, between the view of Broom and Fawcett that the human clavicle is a pure membrane bone, and that of other investigators who see in the clavicle a persisting remnant of the old precoracoid.

[1] It is my pleasure to acknowledge the courtesy extended me by Dr. George L. Streeter, of the Carnegie Laboratory of Embryology, in placing the facilities of the laboratory and the series of human embryos in his charge at my disposal during the summer of 1919.

So far as I am aware, there was no prejudicial bent of mind toward either theory, and I am not committed to either side of the controversy by any statement in my published papers on shoulder-girdle problems.

The result of my examination of all the evidence available may be summed up briefly as follows:

A. The material at my command, the Mall Collection, than which there is no better or larger collection of human embryos anywhere to be found, confirmed in all essential particulars the observations of Broom and Fawcett. Ossification begins approximately about the thirty-ninth day and is by two distinct centers, one in the lateral half and one in the medial half of the clavicle. At this time the bony centers are surrounded by the 'peculiar precartilaginous tissue,' which certainly is not hyaline cartilage. It seems quite clear that *the earliest stage of ossification* in the clavicle, both in its medial and lateral halves, *is a dermal ossification*, and that cartilage is entirely lacking at the time of the appearance of the two centers of bony tissue. This one fact was sufficient to justify Broom and Fawcett in excluding the precoracoid as a morphological element of the human clavicle (figs. 10 to 13).

B. In addition to the confirmation above, my special contribution to the subject consists in an attempt to show that the precoracoid has a history so different from that contemplated by those who see in the cartilage the old precoracoid, that this cartilage could not possibly be that element. I have traced the history and homologies of the precoracoid recently (Hanson, Anat. Rec., vol. 19), and the conclusions therein set forth may be recapitulated briefly here.

1. It has been shown by Broom for Australian marsupials, and the author for the American opossum, that in the embryo and fetus of these forms the shoulder-girdle consists of a scapula, clavicle, and two coracoid elements, one of which, the posterior (fig. 2), extends from the scapula to the sternum and is comparable directly with the coracoid of the monotremes. The anterior element of the marsupial fetus is a broad fan-shaped sheet of mesenchyme, of short duration in embryonic life, and is the homologue of the epicoracoid of monotremes.

2. Development shows that the posterior of the two coracoid elements of the fetal marsupial girdle becomes the small rudimentary coracoid process attached to the scapula in the adult, which process undoubtedly is homologous with the same-named process in man. This gives a clear line of genetic relationship from the coracoid process of man to the posterior element in the girdle of the monotremes.

3. Gregory and Camp ('18) and the author have shown that the conditions in the monotreme girdle are so clearly reptilian in character and approximate so closely in every respect to the structure of the girdles in Sphenodon and lizards that genetic relationship and homology exist between them.

4. Williston ('11) has practically demonstrated that the coracoid of living reptiles is derived from the anterior bony coracoid element (precoracoid) of Permian reptiles.

5. Therefore, if the coracoid process of man is the same element as the posterior coracoid of monotremes, and this latter is directly comparable with the posterior of the two coracoids of Sphenodon and lizards, which is in turn a derivative of the precoracoid of Permian reptiles, then the coracoid process of man equals the anterior bony element of Permians, and *the precoracoid is the true coracoid.*

6. It seems to be pretty well established that the coracoid process of placentals is a precoracoid, so that this bone is fully accounted for without reference to the clavicle. It might be suggested that the part of the precoracoid which has aborted is the piece found in the clavicle, but it has been shown clearly by Broom that the clavicle is fully formed and contains its maximum amount of cartilage long before the degeneration of the precoracoid, i.e., the fully formed precoracoid extending from scapula to sternum (fig. 2) persists for a considerable time after the ossification of the clavicle has begun and the cartilage at its ends is present. The two, fully formed clavicle and precoracoid, are in marsupials coexistent and separated by a considerable space. There is, therefore, no way for the cartilage of the precoracoid to enter the clavicle in mammals.

CONCLUSION

The fact that the cells in the early clavicle are clearly not hyaline cartilage cells, but a peculiar tissue of which little seems to be known, coupled with the demonstration by the author that the well-developed clavicle and complete precoracoid extending from the scapula to the sternum are coexistent in the embryo, and the stages of the degeneration of the precoracoid having been followed completely in marsupials by Broom, excluding the possibility of the entry of precoracoidal tissue into the clavicle, apparently indicates that there are pretty solid grounds for considering the human clavicle to be a purely dermal bone.

PLATE 1

EXPLANATION OF FIGURES

1 Shoulder-girdle and lateral half of sternum and epicoracoidal cartilages of the bull frog. The precoracoid becomes the cartilaginous basis of the clavicle. In this form the clavicle is derived from two sources, the precoracoid and the dermal ossification.

2 Reconstruction of the shoulder-girdle of a marsupial fetus. Note that the coracoid reaches to the sternum. This is the same coracoid that a little later in development aborts, the only remains of which is the rudimentary coracoid process attached to the anterior side of the neck of the scapula. The complete coracoid is present, however, long after the clavicle is fully ossified, and if this element (coracoid) is the precoracoid, as I hold, there is no possibility of its contributing to the cartilage of the clavicle. After Broom.

3 Schematic diagram of shoulder-girdle of man. Compares pretty closely with figure 1 of the anuran shoulder-girdle. However, the resemblance is superficial only (see text) and not genetic. After Huntington.

Resumen por el autor, Frank Blair Hanson.
Universidad Washington, Saint Louis.

El problema del coracoides.

El embrión del opossum americano, Didelphys virginiana posee un coracoides, que, lo mismo que en los monotremas, se extiende hasta el esternón, uniéndose con él en un punto situado entre la clavicula y la primera costilla. Esta última se atrofia y deja un pequeño proceso rudimentario, conocido en el adulto con el nombre de proceso coracoideo.

A la parte descriptiva sigue una discusión de la homología del proceso coracoideo del hombre, esforzándose el autor en demostrar que el proceso coracoideo del hombre es el homólogo del precoracoides de los reptiles fósiles del Pérmico.

THE PROBLEM OF THE CORACOID

FRANK BLAIR HANSON

Department of Zoology, Washington University, Saint Louis, Missouri

TWO PLATES (SEVEN FIGURES)

INTRODUCTION

The phylogeny of the coracoid presents one of the most fascinating and elusive problems of vertebrate morphology. The literature is extensive. The number of conflicting theories and the confusion of the nomenclature is hardly paralleled in the history of any other vertebrate structure. This is due, in part, to its long history, occurring as it does in the Elasmobranchii and found in every group of animals from the dogfish up to man; also, in part, to the radical character of the modifications undergone in the different groups through adaptations to structural and functional demands. A long history of structural changes in a region of progressive functional differentiation, and, complicated further by the presence of both dermal and cartilage bones, gives an ideal situation for exactly what has happened in regard to our knowledge of the coracoid.

One is at times disposed to pigeon-hole this problem among the insolubles, or at least await patiently and in silence for the somewhat remote possibility of turning up some new evidence from paleontological specimens yet to be collected.

However, this is one of those haunting problems that refuses to be pigeon-holed, and, once infected by its appeal, the investigator finds himself returning to it again and again.

DIFFICULTIES OF THE NOMENCLATURE

As indicated above, the nomenclature of the coracoidal elements of the different groups is incredibly involved and confusing. Different authors apply the same name to very different structures, and again different names to the same structure.

In reading the literature on the subject it is necessary, first of all, to ascertain just which element each author has in mind when using the terms metacoracoid, coracoid, epicoracoid, precoracoid, procoracoid, and subcoracoid. As an example of this, Cuvier in 1826 applied the term 'epicoracoid' to the anterior coracoidal element in monotremes. W. K. Parker and others use this same term in speaking of the cartilaginous element on the ventral ends of the coracoids in the frog, alligator, etc., while by Case, Williston and Gregory this same term is used to designate the unossified element found in some fossil reptiles anterior to the two ossified coracoids. A few remarks may clear up the matter somewhat.

In the first place, the term 'epicoracoid' was first given to the anterior element in the monotremes, and by priority should be retained in this connection. The ventral median cartilages of the coracoids of the frog, alligator, etc., have no claim to this name except through the usage of Parker ('67). These cartilages might better have the term 'infracoracoid' applied to them, which would be a suitable and descriptive term and would pair well with the corresponding dorsal cartilage, the suprascapula.

Second, the term 'subcoracoid' may now be discarded. It was formerly applied to the small element on the anterior side of the glenoid fossa in man, and, as its name indicates, was thought to be a vestigial coracoid element. There is now general agreement (infra) that this small bone is a neomorph and not of phylogenetic interest. This disposes of one term from the list

Third, the terms 'precoracoid' and 'procoracoid' are synonymous, some authors preferring one and some the other, while a few use them interchangeably. By pre- or pro-coracoid is understood the anterior of the two ossified elements of Permian reptiles, but not the most anterior of all, which is a cartilaginous epicoracoid (infra).

Fourth, 'metacoracoid' is the name given by Williston to the most posterior coracoid of the Permian reptiles.

Fifth, the simple term 'coracoid' has been so long applied to the coracoid process of man, that it must be retained in this service and its ancestry sought either in the metacoracoid or precoracoid of Permian fossils.

If Broom and Watson are correct in their contention that the metacoracoid of Permians is the homologue of the coracoid process of man, then the metacoracoid is the true coracoid. On the other hand, if the arguments set forth in this paper are valid, the precoracoid is the true coracoid of man.

An examination of the shoulder-girdle of Moschops (fig. 5) will give the correct names of these coracoid elements and their relations to one another when all are present.

THE MARSUPIAL CORACOID

Broom ('97, '98, '99, '02, '12), in a series of papers on the shoulder-girdle of the Australian marsupials, has demonstrated that in all the genera studied by him the coracoid extends to and connects with the sternum during early developmental stages.

This embryonic coracoid extends from the anterior part of the glenoid cavity to a position on the sternum between the clavicle and first costal cartilage. In the earliest stages there are no sutures between these parts (scapula, coracoid, sternum), but the whole is one continuous mesenchymatous and later precartilaginous mass.

The adult marsupial has only a small rudimentary coracoid process (fig. 7) attached to the scapula, not relatively larger than in the higher mammals and man. The transition between the condition in the embryo and that in the adult form is, according to Broom, by a process of degeneration, beginning near the middle portion of the fetal coracoid. This progresses in each direction, completely destroying the sternal half, but only incompletely destroying the scapular half, leaving the well-known rudimentary coracoid process of the adult attached to the anterior side of the neck of the scapula.

This embryonic coracoid of the marsupial has on its anterior border a 'fan-shaped cellular element' which does not participate in the glenoid and is of even shorter duration than the posterior element. Broom considers this anterior element to be an epicoracoid and homologous to the element in the monotremes known by this name and having precisely the same shape, position, and relations.

The posterior fetal coracoid of the marsupial has exactly the same position and relations to the scapula, clavicle, and sternum as has the posterior coracoid in monotremes, and the two are quite certainly homologous.

It appears from this work of Broom that *the embryonic shoulder-girdle of the Australian marsupial is identical with the adult girdle of the monotreme.* I state this strongly at the outset because of the bearing it seems to have upon the whole question of the homology of these elements. In this identity is wrapped up one of the clues to the homology of the coracoid process of man.

Formerly it was impossible to pass from the reptilian-like girdle of the monotremes, with its coracoid complete from scapula to sternum, up to the girdle of the adult marsupial, and higher mammals, with a mere rudimentary process attached to the scapula. The development of the marsupial, however, demonstates in the clearest manner how the coracoid process of the adult passes through a monotreme-like stage with a coracoid extending from sternum to scapula, and how by absorption and degeneration all is lost except the small process on the adult scapula.

Since the work of Broom has an important bearing upon the solution of the long-vexed question of the phylogeny of the coracoid process of man, the question may arise whether his observations and interpretations are correct. Watson ('17), a very careful worker, has verified Broom's results in at least one species of marsupial, Trichosurus. Watson made reconstructions in wax of the parts under discussion and showed that conditions were exactly as described by Broom.

Recently I have had the opportunity[1] to examine several series of transverse and frontal sections of Didelphys virginiana, the American opossum, and have found that in our native marsupial as in his Australian relatives the coracoid is a solid bar of mesenchyme and later of young cartilage cells, extending without sutures from the scapula to a point on the sternum between the clavicle and first rib (figs. 1 and 2).

[1] My appreciation is hereby expressed to Dr. J. L. Bremer, of the Department of Anatomy of the Harvard Medical School, for the privilege of examining the marsupial slides in the Harvard Embryological Collection.

In older stages the coracoid has parted company with the sternum, and that process of absorption, described by Broom for the species studied by him, has begun, which will eventually leave it in the adult but a mere finger-like projection on the anterior neck of the glenoid (fig. 7).

Since the shoulder-girdle of the American opossum was found to be in all essential aspects the exact counterpart of the anterior girdle in its cousins of Australia, no detailed description is necessary here, and I may proceed at once to the discussion of the homology of the coracoid process of man.

THE HOMOLOGY OF THE CORACOID

Broom ('99) in describing the shoulder-girdle of a 17-mm. mammary fetus of the marsupial Trichosurus, says of the coracoid that it is of "much the same absolute size as in the 14.8 mm. stage, and is thus considerably smaller relatively." Broom's work on many species of marsupials shows that as development proceeds the coracoid which once reached the sternum in the embryo and fetus is in the adult only a small process attached to the scapula.

I have observed much this same thing in higher mammals where the coracoid process is relatively much larger in the embryonic stages than in the older fetal stages. Even in the pig, which in the adult has no coracoid process, a small coracoid is present in the embryo and diminishes in size with development. This is also strikingly true in the mouse and human embryos.

Broom has demonstrated conclusively that the coracoid process of adult marsupials is a persisting rudiment of the coracoid which in the fetus extends from the scapula to the sternum. The coracoid of marsupials, therefore, is homologized definitely with the coracoid process of higher mammals and man on the one hand, and with the posterior of the two coracoid elements in the montremes, for in all their morphological relations the two coracoidal elements of the fetal marsupial can be compared directly with the two coracoids of the monotreme. Thus the homologies of the mammalian coracoid may be stated as follows: the anterior and posterior elements of the monotreme girdle are the epicoracoid and coracoid, respectively; and these are the

homologues of the two similar elements found by Broom in Australian marsupials; and the author in the American species.

The anterior of these two elements (epicoracoid) in the monotremes is a permanent feature of the adult skeleton, but disappears in the adult marsupial and does not reappear in higher forms. The posterior element, the coracoid, is a stout element in the monotremes and is present in the adult as in the fetus, while its marsupial homologue is the exact counterpart in the fetal condition, this later gives way through degeneration to the relatively small element (fig. 7) attached to the scapula in the adult. The coracoid process of mammals is, therefore, the homologue of the strong posterior coracoidal bar which connects with the sternum in the monotremes. That this is the correct view of the coracoid homologies between monotremes and marsupials and higher orders of mammals probably will not be seriously questioned.

In passing from the monotremes to the reptiles there is a variety of opinion which is quite revealing of how little after all we have grasped of the real phylogeny of the mammals.

Broom derives the present-day reptiles from a line of Permian ancestors in which the posterior coracoid was gradually lost, leaving the coracoid of Sphenodon, lizards, and the single coracoid of the alligator as the homologue of the anterior coracoid element of the Permians. He, then, derives the mammals from another line of Permian stock in which just the reverse process occurred, i.e., the anterior element now is thought to be the one lost and the posterior retained and homologous with the posterior element of monotremes and the coracoid process of other mammals.

Williston ('11) admits the possibility, and even the probability, of two divergent lines of evolution, one in which the posterior coracoid is lost and leading to present-day reptiles, and one in which the anterior coracoid is lost, leading to the mammals, and he also points out that the absence of the coracoid foramen in the mammals may indicate that this has been the case. However, Williston is very positive that the coracoid of Lacertilia, Dinosauria, Crocodilia, etc., is absolutely identical with the cora-

coid of Seymouria and Varanosaurus, which is without doubt the anterior coracoid. He says:

there cannot be the least doubt but that the posterior bone, the so-called coracoid, is unossified in Seymouria, as in Varanosaurus. . . . The coracoid of all these forms consists exclusively of the anterior element, the so-called procoracoid. That this bone has entirely disappeared in all later reptiles, giving place in its entirety to another bone, here unossified, with like attachments, and with its perforating supracoracoid foramen in the same position, I cannot believe. It seems to me utterly improbable that the coracoid as ossified in the Seymouria and Varanosaurus is not identical with the bone supposed to be (without proof) the fused coracoid and procoracoid of Lacertilia, Dinosauria, etc., ... the only thing I wish to insist upon is that the coracoid of Seymouria and Varanasaurus is absolutely identical with the coracoid of the Lacertilia, Dinosauria, Crocodilia, etc.

Again discussing this same point under the genus Varanosaurus, Williston says:

the absence of a posterior bone in this genus, as in Seymouria is remarkable. The whole pectoral girdle of Varanosaurus has an almost absolute superficial identity with that of the lizards. Under the usual interpretation, however, the large ossified coracoid of Varanosaurus, with its close resemblance to the coracoid of Varanus, for instance, in its supracoracoid foramen and fenestra, is the metacoracoid. In other words it is assumed that the coracoid of Varanosaurus has disappeared gradually by the encroachment upon it of the posterior bone, the so-called true coracoid, which here in this genus was so degenerate that it no longer was even ossified. It seems to me that the utter absence of any proof that such has been the course of evolution in the pectoral girdle of reptiles—for no intermediate form has ever been discovered, no form in which the posterior bone has even reached as far forward as the supracoracoid foramen—is sufficient to throw great doubt upon the hypothesis, a doubt that becomes quite conclusive in the proof afforded by the various specimens of these and other Permian reptiles.

It is a curious fact also that a posterior coracoid bone has never been observed in any temnospondyl, though the sutural division between the scapula and coracoid I have observed in specimens referred to Aspidosaurus to be quite as in Seymouria.

Williston's work is quite conclusive in homologizing the coracoid of Sphenodon, lizards, and crocodiles with that of the anterior element (precoracoid) of Permian reptiles.

Is it possible to pass from the lizards and Sphenodon to the monotremes? is the question now facing us. For if we accept the above arguments on the homology of the posterior element of monotremes with the coracoid process of mammals, and also assent to Williston's view that the single coracoid of lizards and Sphenodon is the homologue of the precoracoid of fossil reptiles, then by bridging the gap between monotremes and living reptiles we shall have completed the homology of the coracoid from early Permian reptiles up to man.

Gregory and Camp ('18) have compiled the evidence or given the basis for this latter homology between monotremes and living reptiles. In the first place, it has been shown that the single coracoid of Sphenodon "gives origin on its ventral surface to a group of muscles comprising the biceps and the three branches of the Coracobrachialis, which group appears to be precisely homologous with a similar group of muscles carried by the ventral surface of the coracoid of monotremes." The subcoracohumeralis of Sphenodon arises on the dorsal surface of the coracoid and is homologous with the similarly placed muscle, subcoracoideus, of the monotreme. As far as evidence from muscle goes, the coracoid (= precoracoid) of Sphenodon is identical with the coracoid of monotremes. Secondly, the epicoracoid of Sphenodon and the lizards is widely excluded from the glenoid exactly as in the monotremes and the embryos of marsupials. The relations of the epicoracoid to coracoid, clavicle, and interclavicle are also identical in monotremes and living reptiles, and in each the ventral surface of the epicoracoid carries the anterior part of the supracoracoid muscle. Comparison of the monotreme coracoid with that of the alligator shows practically the same thing. While there is only one coracoidal element (= precoracoid) in the alligator, Gregory thinks that with the loss of the clavicle in this form there undoubtedly also was lost a membranous epicoracoid which lay between the interclavicle and the coracoid. If this should prove to be the case, the identity between the monotreme girdle and that of the Crocodilia is quite complete.

In general, to quote again from Gregory and Camp ('18), "the whole complex of relations of the epicoracoid and coracoid

of monotremes to each other and to the scapula, clavicle, and interclavicle, is practically identical with the relations of the same set of elements in lizards and Sphenodon" (figs. 3, 4, 5, and 6).

There is, then, considerable evidence for comparing directly the coracoid of monotremes with that of living reptiles, and, as shown above, Williston, Broom, Gregory, and Watson unite in homologizing the single coracoid of crocodiles and Sphenodon and the posterior element in lizards with the precoracoid of Permian reptiles.

If this reasoning is valid, then the coracoid process of man is a precoracoid and the homologue of the single coracoid of such Permians as Seymouria and Varanosaurus, and likewise homologous to the anterior element of those Permians which possess two bony coracoids.

Another question yet remains to be disposed of. If the coracoidal elements of the monotremes, Sphenodon, and the lizards are the homologues of the anterior element of Permian reptiles, what is the phylogeny of the so-called anterior element or epicoracoid of living reptiles and monotremes? Only one explanation has been offered, and that by Gregory and Camp, to the effect that in such a Permian as Moschops (fig. 5) and probably in others, there was really an epicoracoidal cartilage present between the precoracoid and the clavicle and interclavicle. At least in fitting the bones of the shoulder-girdle of Moschops together, it was found that there was a space between the clavicles, interclavicle, and precoracoids which must have been filled by the epicoracoids as in Sphenodon, lizards, and monotremes. The same thing is indicated in Eryops. As shown above, the epicoracoid, often appearing transiently as an embryonic structure in the marsupial, disappears from all higher forms.

This means, of course, that according to Gregory there were originally three coracoid elements—metacoracoid, precoracoid, and epicoracoid—rather than the two usually considered. The admission of a third coracoid (epicoracoid) is denied by Watson, who says (in a private letter) "that the presence of a distinct ossified 'epicoracoid' (as a third anterior element) in Permian vertebrates has never been proven."

While the existence of a third epicoracoidal element has not been proved by the demonstration of an actual specimen from Permian strata, there are several strong indications that such might have been the case. One of these has already been mentioned, namely, that in the Permian Moschops between the precoracoid, clavicle, and interclavicle, there is a space directly comparable with the one filled by an epicoracoid in the lizards and Sphenodon. Since the epicoracoid is a broad thin plate of membranous tissue, it naturally would be lost in the process of fossilization. Other evidence that the epicoracoid was a fairly constant element of Permian reptiles is furnished by Case ('07, '11 a, '11 b). Describing the skeleton of Dimetrodon dollovianus, he says, "the procoracoid terminates anteriorly in a thin, straight edge, which shows signs of having borne a heavy epicoracoidal cartilage." Dimetrodon has an ossified coracoid and a precoracoid, and if Case is correct, it also carried a heavy cartilaginous epicoracoid on the anterior edge of the precoracoid. Since the cartilage would not be preserved, we have probably as near a demonstration of the presence of three coracoidal elements (metacoracoid, precoracoid, and epicoracoid) in Permians as will ever be obtained. That this is not an isolated case is shown in two other illustrations taken from Case.

Describing the genus Diadectes Cope, Case ('11 a) says of the shoulder-girdle, "the coracoid and precoracoid are not separated from the scapula by suture. . . . The anterior edge (of the precoracoid) is nearly straight and shows the attachment of a *cartilaginous epicoracoid* of considerable size." And again, Case ('11 b), quoting Cope's description of Eryops megacephalus, gives the following account of the girdle: the coracoid is but little incurved; its internal border is convex, and is roughened as though for cartilaginous attachment. Its superior portion forms a convex continuum with the scapula. The direct line or external face of the scapula extends in a nearly plane surface to the glenoid cavity, embracing a perforating foramen above the latter, precisely as in the Pelycosauria. Its surface is continuous anteriorly with a wide expansion forwards, whose fine inner border is continuous with that of the coracoid. This plate doubtless

includes a third element, but its borders are not preserved, on account of the obliteration of the sutures. It is probably *epicoracoid*, as in the Pelycosauria.

From the foregoing, it is apparent that in several groups of Permian reptiles and in the primitive Eryops, there is considerable evidence to support the theory of a third coracoidal element —the epicoracoid in front of the precoracoid.

The following table shows the presence or absence of these several coracoidal parts in fossil and living forms according to the interpretation of the homology of the coracoid herein set forth.

	METACORACOID	PRECORACOID	EPICORACOID
Eryops	*	*	*
Moschops	*	*	*
Dimetrodon	*	*	*
Diadectes	*	*	*
Seymouria		*	
Varanosaurus		*	
Sphenodon		*	*
Lizards		*	*
Alligator		*	
Monotreme		*	*
Marsupial fetus		*	*
Marsupial adult		*	
Man		*	

* = element is present.

While the above table is not in any sense a phylogenetic one, it shows that in several groups of Permian fossils, relatives to the ancestors of the mammals, three coracoidal elements were present, and by *the dropping out of either the most posterior element (metacoracoid) or the most anterior element (epicoracoid), or both of these elements*, all the variations met with from Permians to man are explicable.

The relations and homologies here set forth will stand regardless of what disposition is finally made of Gregory's "epicoracoid or third coracoid element," for the homologies of the coracoid all hinge upon the precoracoid as the constant and vital factor in the phylogenetic succession.

The epicoracoid may be, for all anyone has shown to the contrary, merely a neomorph, like the subcoracoid, with no morphological significance. Regardless, then, of the fate of the epicoracoid, the following homology apparently is established, namely, that *the precoracoid of Permians = coracoid of living reptiles = coracoid of monotremes = coracoid of marsupials = coracoid process of man.*

It is at once apparent that the precoracoid of Permian reptiles is the constant factor in the situation. Since, as shown by Williston, this element (precoracoid) is the one preserved and known as the coracoid of Sphenodon, lizards, and the alligator, the term coracoid is correctly applied only to the homologues of the precoracoid. Gregory and the author have argued for the homology of the girdles of Sphenodon and lizards with that of the monotremes, and Broom and the author have shown that the conditions in the monotremes are directly comparable with the fetal girdle of the marsupials, therefore, the two elements of the girdle in the fetal marsupial (coracoid and epicoracoid) are homologous with the same two elements in the lizard and Sphenodon. But these elements of Sphenodon and the lizards are demonstrated by Williston and Case to be the homologues of the precoracoid and cartilaginous third element (epicoracoid) of Permian reptiles. Therefore, again, the two elements of monotremes and fetal marsupials are homologues of the precoracoid and cartilaginous epicoracoid of Permian reptiles, and not to the precoracoid and metacoracoid, as assumed by Watson and Broom.

In the fetal marsupial the epicoracoid is embryonic only, the coracoid aborts except for a small rudimentary process attached to the scapula, which is undoubtedly the homologue of the same-named element in higher mammals and man. Therefore, once again, the coracoid process of man is a precoracoid and the homologue of the precoracoid of fossil reptiles.

It may be objected that the precoracoid of Permian reptiles, and its homologue in living reptiles, carried a foramen and nerve. This is not present in monotremes, and we must assume it to be lost here. This is not a serious objection, as the foramen is also absent from the coracoid of many birds, which coracoid is without question the homologue of the precoracoid.

Also it may be pertinent to ask, if the coracoid process of placental mammals is the posterior element of Permians, how did it get to the anterior side of the glenoid? It is hard to imagine any rotation or migration of this element which would bring it from a position distinctly posterior of the glenoid to its present distinctly anterior position.

THE SUBCORACOID

The subcoracoid center of placental mammals has been homologized by Howes ('93), Lydekker ('93), and others to the metacoracoid of Permian reptiles. They regard the subcoracoid center of mammals as the vanishing vestige of the metacoracoid. Gregory ('15) and also Williston formerly accepted this homology, but Gregory ('18) has reconsidered this element and now believes it to be a neomorph or cartilaginous epiphysis and without morphological significance.

Hanson ('19), in studying this subcoracoidal element in the pig (an animal lacking the coracoid process), came to the conclusion that this center of ossification in the pig was an epiphysis.

The subcoracoid always occupies the anterior portion of the glenoid, just behind the coracoid process. The posterior part of the glenoid in mammals is formed by the lower end of the scapula. To accept the subcoracoid element as the last remaining rudiment of the metacoracoid, it would be necessary to assume that in some way there was a rotation of the scapula so that the posterior side of the glenoid in Permian reptiles is now the anterior side of placental mammals, or else in some manner that this center has migrated across the glenoid cavity anteriorly to its present position. Either of these explanations puts our credulity under a rather heavy strain.

Gregory and Camp ('18) also point out in this connection that the subcoracoid "is located at the anterior end of the glenoid ligament where the latter is continuous with the tendon of the biceps . . . . . as the intrascapular position of part of the biceps is undoubtedly a neomorph in the placentals, we suggest that the appearance of a subcoracoid is also a neomorph."

Broom was the first to suggest that the subcoracoid was an epiphysis, and not part of the coracoid complex.

SUMMARY

1. It has been shown by Broom for Australian marsupials and the author for the American opossum that in the embryo and fetus, the shoulder-girdle consists of a scapula, a clavicle, and two coracoidal elements, one of which, the posterior, extends from the scapula to the sternum and is comparable directly with the coracoid of monotremes. The anterior element of the marsupial fetus is a broad fan-shaped sheet of mesenchyme, of short duration in embryonic life, and is the homologue of the epicoracoid of monotremes.

2. Development shows that the posterior of the two coracoidal elements of the fetal marsupial girdle becomes the small coracoid process attached to the scapula in the adult, which process undoubtedly is homologous with the same-named process in man. This gives a clear line of relationship from the coracoid process of man to the posterior element in the girdle of the monotremes.

3. Gregory and the author have maintained that the conditions in the monotreme girdle are so clearly reptilian in character and approximate so closely in every respect to the structure of the girdles in Sphenodon and the lizards, that genetic relationship and homology exists between them.

4. Williston has practically demonstrated that the coracoid of living reptiles is derived from the anterior bony element (precoracoid) of Permian reptiles.

5. Therefore, if the coracoid process of man is the same element as the posterior coracoid of monotremes, and this latter is directly comparable with the posterior of the two coracoids of Sphenodon and lizards, which is in turn a derivative of the precoracoid of Permian reptiles, then the coracoid process of man equals the anterior bony element of Permians, and *the precoracoid is the true coracoid.*

6. The subcoracoid of placental mammals is not a coracoid element at all, but an epiphysis, and does not enter into the problem of the coracoid.

Resumen por el autor, Homer B. Latimer.
Universidad de Nebraska.

Peso de las vísceras en la tortuga.

Veintiún machos y una hembra de la tortuga de Cumberland (Chrysemis elegans) fueron empleados en el presente trabajo. Después de cloroformizados se pesaron, disecándoles a continuación y extrayendo las vísceras, que se pesaron, en frascos de pesar con tapón de vidrio, en una balanza química que podía apreciar diferencias de una décima de miligramo.

El peso ordinario de las vísceras expresado en tantos por ciento del peso total es el siguiente: el corazón, 0.31; el bazo, 0.21; los pulmones y tráquea, 1.07; el tubo digestivo sin su contenido, 6.23; el hígado, 5.43; el páncreas, 0.15; los riñones, 0.31; y los testículos 0.23 por ciento, o sea un total de 13.74 por ciento del peso total del cuerpo.

Cuando se emplearon los pesos absolutos del cuerpo y de cada órgano para determinar el coeficiente de variabilidad, el autor halló que el peso del cuerpo posee un coeficiente menor que el de cualquiera de los órganos. Los órganos que poseen un coeficiente de variabilidad menor son generalmente los órganos con un coeficiente mas alto de correlación con el peso total del cuerpo. Naturalmente, los coeficientes de variabilidad de los órganos son mas pequeños cuando en vez de los pesos absolutos se emplean los pesos en tantos por ciento. Estos últimos se obtienen reduciendo los absolutos a un por ciento del peso total del cuerpo.

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED
BY THE BIBLIOGRAPHIC SERVICE, OCTOBER 4

THE WEIGHTS OF THE VISCERA OF THE TURTLE[1]

HOMER B. LATIMER

Department of Zoology, University of Nebraska

The frequent use of the turtle for laboratory purposes and the lack of quantitative data on the size of the turtle viscera has made it seem worth while to determine the weights of the viscera of the turtle. Another thing which suggested this problem was the question of the effect of the weight of the turtle shell on the percentage weights of the organs. The only published quantitative work on the turtle viscera of which I am aware is the report of Welcker and Brandt ('03) upon a single female specimen of Testudo graeca. The brain and spinal cord of each turtle were removed, measured, and weighed, and this data will be combined with similar data from other forms and published later.

MATERIAL AND METHODS

The specimens used in this investigation were twenty-one male and one female Cumberland terrapins (Chrysemys elegans), three Southern musk turtles (Aromochelys tristata), one male and two females, and one male specimen of Lesueur's terrapin (Malacoclemmys lesueurii). The turtles were killed with chloroform. The small turtles were weighed on a chemical balance sensitive to a tenth of a milligram, the larger turtles, the Cumberland terrapins, were weighed on a laboratory balance sensitive only to a tenth of a gram. The viscera were carefully dissected out and immediately put in ground-glass-stoppered weighing bottles after all the excess blood had been allowed to drain off. The lungs and trachea were weighed together, the trachea being severed at its attachment to the pharynx. The oesophagus was cut away

[1] Studies from the Zoological Laboratory of the University of Nebraska, no. 126.

from its attachment to the pharynx and the large intestine was severed at its opening into the cloaca. The entire tract was removed with as little of the surrounding fat and the mesenteries as possible. The stomach and intestines were opened and the contents removed. What little material there was in the intestine could usually be forced along the intestine by gentle pressure until it could be removed at the end or at one or two incisions. All the other viscera were removed in a similar manner with as little of the mesenteries and fat as possible. The net body weight and the percentage of loss were not determined as they were for the frogs (Latimer, '20), but in other respects the same plan, which was described in the previous paper, was followed in the dissection and weighing of the turtles.

The twenty-two Cumberland terrapins were received from a Chicago dealer, and the fact that but one of the twenty-two was a female is interesting. They were kept in a tank with free access to running water in a room with a temperature slightly below the usual laboratory temperature. The first turtle was killed and studied December 23, 1919, or soon after they were received. The last one was killed January 26, 1920. They received no food during this time, and when killed only small masses of fecal material were found toward the caudal end of the intestines. They all had ample quantities of fat in the mesenteries, showing that they were in good condition.

PERCENTAGE WEIGHTS OF THE VISCERA

Table 1 A gives the total weight in grams of each of the twenty-one male Chrysemys elegans and the weights of the viscera of each turtle expressed in percentages of the total body weight. Sections B, C, and D give the same data for the one female Chrysemys elegans and for the other turtles. The weights of the digestive tract are for the empty tract. There was so little material to be removed that no correction was made for this in the total body-weight.

Table 2 will facilitate comparisons between the turtles and other species. It shows the averages of the percentage weights

of the various organs of the turtles and the same data for the other forms. The first line gives the average percentage weight of the organs of the twenty-one male turtles (*C. elegans*). The second line gives the averages for the three Southern musk turtles, and the third line the percentage weights of the viscera of the one Lesueur's terrapin. The data for the first three lines are taken directly from table 1. The percentage weights for the Testudo graeca are taken from the report of Welcker and Brandt ('03) and are for a single female specimen. The next two lines give the average percentage weights of the organs of the ten male and nineteen female frogs (*Rana pipiens*) from a previous paper (Latimer, '20). The percentages of the rat viscera are those given by Jackson ('13) for one-year-old male white rats. The last line gives the data on the human organs as given by Vierordt ('06). The last column of the table shows the totals of the percentage weights for all the viscera of each species. These were determined from the four-place decimals of the complete tables, and consequently the sums are slightly larger than the sums of the two-place decimals given in this table. It is obviously impossible to place much weight on the figures in the second, third, and fourth lines, for these three lines represent altogether but five specimens.

In comparing the twenty-one male turtles with the frogs it is apparent that each of the organs of the turtle is heavier than the same organ of the frog, with the exception of the heart and the kidneys.

Heart. The heart forms a smaller percentage weight in the turtles than in any of the other forms. Joseph ('08) suggests that the relative size of the heart is correlated with the activity of the animal. This would place the turtle at the bottom of the list as far as activity is concerned, and the Chrysemys elegans would be more active than the other three species of turtles, if we may be permitted to judge from the very small numbers. The percentage weights of the heart for the frog, the rat, and the human are nearly the same.

Spleen. The spleen is the most variable organ not only in comparing the eight species listed in this table, but in comparing

the individual twenty-one male turtles and the twenty-nine frogs. It is thirteen times heavier in the rat than in the three musk turtles.

Lungs. The weights of the lungs in terms of percentage of the total body weight are heavier in the turtle than in the frog. In weighing the turtle lungs the trachea is included. This might account for the difference, but the turtle *lung* is a more complicated structure than the simple sac-like lung of the frog. No separate weighings of the trachea were made.

Digestive tract. The digestive tract in the Cumberland terrapins, Testudo graeca, and the white rat is much heavier than the

TABLE 2

Showing the average percentages of the viscera for the following species

	HEART	SPLEEN	LUNGS	DIGESTIVE TRACT	LIVER	PANCREAS	KIDNEYS	TOTALS
C. elegans	0.31	0.21	1.07	6.23	5.43	0.15	0.31	13.74
Musk turtle	0.28	0.03	0.92	3.38	2.40	0.14	0.27	7.45
Lesueur's terrapin	0.24	0.18	1.14	3.11	3.75	0.13	0.24	8.83
Test. graeca	0.23	0.10	1.71	5.68	5.78	0.14	0.62	14.26
Male frogs	0.43	0.18	0.85	3.50	2.80	0.09	0.43	8.31
Female frogs	0.47	0.16	0.76	3.77	2.88	0.09	0.47	8.63
White rat	0.45	0.39	0.93	5.1	4.42		0.95	12.25
Human	0.46	0.25	1.50	2.06	2.75	0.15	0.46	7.63

percentage weights in the other forms. The lower percentages in the frogs, the musk turtles, and Lesueur's terrapin may have been due to the fact that they were kept in the laboratory for some time before being killed. The Cumberland terrapins were kept in the laboratory for only a little over one month, and that was during the winter time, while the frogs and the other turtles were kept for a longer time and during the summer. It is interesting to note that the percentage weight of the human digestive tract is the lowest and that of the Cumberland terrapin the highest, or a little over three times the percentage of the human digestive tract.

Liver. The variation in the percentage weights of the liver in comparing one form with another seems to parallel the varia-

tion in the digestive tracts. The human, the Testudo graeca, and Lesueur's terrapin are the only forms in which the liver is heavier than the digestive tract. Only five of the twenty-one male turtles had a liver with a heavier percentage weight than the digestive tract.

Pancreas. The pancreas forms nearly the same per cent in all forms except the frogs, where it is much less.

Kidneys. The kidneys show a marked variation, the kidneys of the rat being 3.95 times heavier than the kidneys of the Lesueur's terrapin. The kidneys of the three terrestrial forms, the rat, the human, and the Greek tortoise, are heavier than the kidneys of the aquatic forms. The adrenals were included in the weights of the kidneys of the turtles which I weighed, and of the frogs.

A comparison of the sums of the percentage weights of the viscera of the turtle (C. elegans) and the frogs is interesting, the former being 1.6 times heavier than the latter. This means that either the organs of the turtle are relatively larger than those of the frog or that the better-developed musculature or other parts of the frog more than compensate for the shell of the turtle. The sum of the percentages for the human most nearly resembles the sum of the percentages of the musk turtles, which were undoubtedly undernourished, due to their prolonged period in the laboratory, and the normal healthy rats resemble more closely the sum of the percentages of the turtle. If we omit the one specimen of the Greek tortoise, we find the viscera of the Cumberland terrapin the heaviest, with the weights of the viscera of the white rat a close second.

COEFFICIENTS OF VARIABILITY

In table 3 are shown the coefficients of variability of the percentage weights of the viscera of the twenty-one male Cumberland terrapins and of the ten male and nineteen female frogs. The coefficient of variation and the probable error of the coefficient of variation for the turtles are taken from table 1. The coefficient of variation and the probable error of the coefficient of variation for each organ of the frogs were computed from the

data given in table 2, page 39, of the report of the frog viscera (Latimer, '20), which gives the percentage weights of the viscera of the chloroformed frogs, Rana pipiens. In finding the standard deviation, the coefficient of variation and coefficient of correlation and the probable errors of each of these, Pearson's formulae, as given by Davenport ('04), were used. A six-place logarithm table and the table of squares given by Davenport ('04) aided in the computations. All the results were checked.

This table shows the turtle spleen with a coefficient of variation of 33.46 ± 3.85 or four times that of the digestive tract. The frog spleens have a still higher variability, or 71.0 ± 15.1

TABLE 3

Coefficient of variability of percentage weights

MALE TURTLES		MALE FROGS		FEMALE FROGS	
Digestive tract	8.05±0.84	Kidney	11.5±1.7	Kidney	12.9 ± 1.4
Liver	9.42±0.98	Digestive tract	12.6±1.9	Liver	19.6 ± 2.2
Heart	10.83±1.27	Heart	13.4±2.0	Lungs	20.7 ± 2.3
Kidney	12.43±1.31	Liver	15.4±2.3	Digestive tract	21.6 ± 2.4
Pancreas	23.12±2.47	Lungs	17.7±2.7	Heart	22.2 ± 2.5
Lungs	27.03±2.91	Pancreas	22.2±3.5	Pancreas	24.5 ± 2.8
Spleen	33.46±3.85	Testes	47.2±8.5	Ovaries	52.1 ± 7.0
Testes	35.65±4.15	Spleen	71.0±15.1	Spleen	64.7 ± 9.6

for the male and 64.7 ± 9.6 for the female frogs. This it will be seen is greater than the coefficient of variation of either the testes or the ovaries of the frog. The low coefficient of variation of the digestive tract of the turtle is noticeable, due possibly to the lack of food for a similar length of time and uniform conditions of temperature and so forth. The kidney, which is fourth in variability in the turtle, ranks first with a variability of 11.5 ± 1.7 in the male and 12.9 ± 1.4 in the female frogs. The pancreas seems to be about the same in all three columns, with a coefficient of variation of 23 for the turtles, 22 for the male frogs, and 24 for the female frogs. The ovaries, as might be expected, show a greater variability than do the testes, and both gonads of the frogs show a greater variation than do the testes of the

turtles. The heart is third in two columns and fifth in the third, the lungs are sixth in order of the increasing coefficient of variability in the turtle, fifth in the male frogs, and third in the female frogs.

Table 4 gives the data for the weights of the organs in grams; A gives the data for the twenty-one male turtles and B for the

TABLE 4

Showing average weights, standard deviations, and coefficients of variability, computed from the actual weights of the organs in grams

	AVERAGE WEIGHT	RANGE	STANDARD DEVIATION	COEFFICIENT OF VARIABILITY

Liver	1.0945	0.5299–2.2951	0.382	34.97 ± 3.45
Pancreas	0.0372	0.0138–0.0670	0.013	35.43 ± 3.51
Kidneys	0.1735	0.0990–0.2762	0.044	25.89 ± 2.44

ten male and nineteen female frogs taken together. The first column gives the average weights, the second the range or the lowest and highest weight, the third column gives the standard deviation, and the fourth column, the coefficient of variability and probable error of the coefficient of variability for each organ.

In preparing the data for table 3 each individual organ of each specimen was reduced to a percentage weight of the total body

weight of the animal, and so any variation in the weights of the organs due to a variation in the size of the specimen was eliminated. In table 4 the actual weights of each organ were used in the computations. This naturally would make the coefficients of variability larger when the absolute weights are used than when the percentage weights are employed, and is evident from a comparison of tables 3 and 4. It is an interesting fact that the total body weight for both the turtles and the frogs has a lower coefficient of variability than any of the individual organs. Since the entire animal varies less than any of the individual organs, it would seem that there might be some reciprocal relationship between at least some of the organs, but as will be explained below nearly all the correlations are positive (table 5).

The turtle heart has nearly the same coefficient of variability in each table, 10.83 for the percentage weights and 11.06 for the absolute weights. The digestive tract comes second in order of increasing coefficients of variability of the viscera, with a coefficient of 13.19 in this table compared with a coefficient of 8.05 in the preceding table. The kidneys of the frogs still retain their position as the least variable in the list of the organs of the frog, and the spleen is the most variable, having a coefficient of 38.36 for the turtles as compared with 33.46 for the percentage weights. The pancreas and lungs are about the same, but all of the other organs of the turtle have a higher coefficient of variability in table 4 except the testes and for this organ the percentage weights give a coefficient of variation of 35.65 ± 4.15, and the absolute weights a coefficient of 34.58 ± 4.00. This is probably due to the fact that there is practically no correlation between the weight of the testes and the total body weight (table 5), and consequently the reduction of the absolute weights of the testes to a percentage of the body weight would not give even as constant a series as the absolute weights themselves. The greatest increase is found in the liver of the turtle. It has a coefficient of variability in the table of percentage weights of 9.42 ± 0.98 and 19.66 ± 2.12 in the table of absolute weights. The liver has a rather close correlation with the body weight (table 5), and so although it is a rather variable organ, reducing its weight to a

percentage of the total body weight reduces its variability. The pancreas and lungs, which are about the same in tables 3 and 4, have a low coefficient of correlation with the total body weight and consequently reducing them to a percentage basis makes but little difference with their coefficients of variation.

The same relationship between the coefficients of variability (tables 3 and 4) and the coefficients of correlation of the various organs with the total body weight (table 5) holds good for the frogs as well as for the turtles. For all of the organs of the frog except the spleen, the coefficients of variability for the percentage weights is less than the coefficients for the absolute weights, and for all of these organs table 5 shows a rather good coefficient of correlation with the body weight. The spleen has a negative correlation of 0.064 and its coefficient of variation for the twenty-nine male and female frogs taken together and using the absolute weights of the spleen is 59.95, but when the percentage weights are used the spleens of the male frogs have a coefficient of variability of 71 and the female a variation of 64.7.

COEFFICIENTS OF CORRELATION

The coefficients of correlation of the absolute weights of the individual organs and the total body weight for the twenty-one male turtles and the ten male and nineteen female frogs, taken in one group, are given in table 5. As has been suggested above, the organs having a close correlation with the total body weight have a lower coefficient of variation when the percentage weights are used than when the absolute weights are employed.

The correlations between the body weights and the individual organs seem to be a little closer for the frogs than for the turtles. The body weight and the pancreas of the frogs have a positive correlation of 0.909, while in the turtles the correlation of the same organ and the body weight is but + 0.391 and the highest coefficient of correlation is + 0.794 for the digestive tract and the body weight of the turtle. The only negative coefficient of correlation of any of the organs with the body weight is that of the spleen of the frog. The testes, lungs, and pancreas of the turtles have very low coefficients of correlation with the body weight.

In table 5 B are shown the coefficients of correlation between some of the organs, both for the turtles and for the male and female frogs. As in the preceding part of the table the correlations are closer for the organs of the frogs, the digestive tract and kidney having a correlation of + 0.875, while the same organs

TABLE 5

Coefficients of correlation

TWENTY-ONE MALE TURTLES		TWENTY-NINE FROGS (MALE AND FEMALE)	
A. Correlations with body weight			
Body weight and digestive tract	+ 0.794 ± 0.054	Body weight and pancreas	+ 0.909 ± 0.021
Body weight and liver	+ 0.632 ± 0.088	Body weight and digestive tract	+ 0.866 ± 0.031
Body weight and kidneys	+ 0.613 ± 0.098	Body weight and kidneys	+ 0.863 ± 0.031
Body weight and heart	+ 0.535 ± 0.105	Body weight and liver	+ 0.845 ± 0.035
Body weight and spleen	+ 0.432 ± 0.119	Body weight and lungs	+ 0.733 ± 0.057
Body weight and pancreas	+ 0.391 ± 0.156	Body weight and heart	+ 0.665 ± 0.069
Body weight and lungs	+ 0.158 ± 0.143	Body weight and spleen	− 0.064 ± 0.124
Body weight and testes	+ 0.089 ± 0.146		
B. Correlation of organs			
Liver and spleen	+ 0.731 ± 0.068	Digestive tract and kidneys	+ 0.875 ± 0.029
Liver and kidneys	+ 0.648 ± 0.085	Digestive tract and heart	+ 0.858 ± 0.045
Liver and pancreas	+ 0.626 ± 0.089	Digestive tract and liver	+ 0.725 ± 0.059
Digestive tract and kidneys	+ 0.619 ± 0.090	Pancreas and liver	+ 0.657 ± 0.071
Spleen and pancreas	+ 0.452 ± 0.117	Kidneys and liver	+ 0.654 ± 0.071
Digestive tract and liver	+ 0.362 ± 0.127	Kidneys and lungs	+ 0.530 ± 0.090
Digestive tract and heart	+ 0.254 ± 0.137	Heart and lungs	+ 0.396 ± 0.105
Digestive tract and spleen	+ 0.253 ± 0.137	Pancreas and spleen	− 0.108 ± 0.123
Lungs and kidneys	+ 0.228 ± 0.139	Liver and spleen	0.0
Lungs and heart	+ 0.143 ± 0.144	Digestive tract and spleen	− 0.025 ± 0.125

of the turtles have a positive correlation of but 0.619. The three highest coefficients of correlation between the organs of the turtles are between the liver and spleen, liver and kidney, and the liver and pancreas. The three closest correlations in the frog viscera are the digestive tract and kidney, digestive tract and heart, and the digestive tract and the liver. All the coefficients of correlation are positive for the turtle viscera, although some of them are very low, but for the frog viscera two of the correlations are negative, although low and one is zero. The liver and spleen of the frogs have a coefficient of correlation of zero, and yet for the same organs in the turtle we find the highest correlation of any of the organs, or + 0.731. The two negative correlations for the frog viscera are the spleen and pancreas and the spleen and digestive tract. Both of these correlations are low in the turtle viscera.

SUMMARY

1. The heart of the male turtles (C. elegans) forms 0.31 per cent of the total body weight. It has the lowest coefficient of variability of any of the organs, or 11.

2. The spleen equals 0.21 per cent of the total body weight and is the most variable of the organs, having a coefficient of variability of 38.

3. The lungs which compose 1.07 per cent of the total weight of the turtle have a coefficient of variability of 27.

4. The digestive tract forms 6.23 per cent of the body weight and it has a coefficient of variability of 13.

5. The liver is second largest in percentage weight. It forms 5.43 per cent of the weight of the body and has a coefficient of variability of 19.

6. The pancreas, with a coefficient of variability of 25, forms but 0.15 per cent of the total weight of the turtle.

7. The kidneys form 0.31 per cent of the body weight and have a coefficient of variability of 16.

8. The gonads are less variable than the spleen, for they have a coefficient of variability of 34 and they form 0.23 per cent of the total body weight.

Resumen por el autor, Otto F. Kampmeier.
Universidad de Illinois.

La circulación colateral en un caso de oclusión completa del orificio de la vena cava superior.

El orificio de la vena precava y de la mayor parte de la cámara atrial de un corazón humano aparecían obstruidos a consecuencia de la formación de un gran trombus en el atrio derecho, sufriendo dicho trombus una calcificación subsiguiente.

Los cambios resultantes en la dirección y marcha de la corriente venosa pueden resumirse brevemente del modo siguiente: Toda la sangre que vuelve al corazon desde la porción del cuerpo situada sobre el diafragma, excepto la procedente de las venas coronarias, tenía que descender, principalmente por el sistema de las venas azigos, a la cavidad abdominal, donde penetraba en la postcava. La dirección de la corriente sanguínea en el sistema de las venas azigos, era pues, completamente contraria a la dirección de la misma corriente en el cuerpo normal. Estas modificaciones se han expresado mediante dos esquemas que acompañan al trabajo.

THE COLLATERAL CIRCULATION IN A CASE OF COMPLETE CLOSURE OF THE MOUTH OF THE SUPERIOR VENA CAVA

OTTO F. KAMPMEIER

Department of Anatomy, College of Medicine, University of Illinois, Chicago, Illinois

TWO FIGURES

The case, here described, is that of a negress of middle age, who died of pneumonia in the course of chronic mania. The body was muscular and well nourished; of short stature, being less than five feet in height, it weighed 150 pounds. Surface examination showed a large ulcer on the lower lateral side of the right leg. This character and certain of the internal abnormalities found later led one to suspect syphilis, which diagnosis was subsequently substantiated by the woman's clinical history at the insane asylum[1] where she had been confined. The records revealed that she was a prostitute and a criminal; she committed murder, evidently in a fit of madness, for she was placed in a hospital for mental diseases (1901) and, fourteen years later (1915), was admitted to the asylum for mentally diseased. The clinical data further showed that she had been under syphilitic treatment for years.

During the dissection[2] of the cadaver, a considerable number of abnormalities were observed, chief of which were those of the heart, to be described presently, also a large fibroid of the uterus, a fairly large lipoma of the back in the lumbar region, softening

[1] Asylum for Mentally Diseased in Wauwatosa, near Milwaukee, Wisconsin. I thank Dr. F. W. Beutler, director of the institution, for looking up the records of the case.

[2] The dissection was carried out by two of my students, Messrs. J. A. Blair and A. J. Raymond, at the Marquette School of Medicine, Milwaukee, and the figures were copied from my diagrams and prepared for publication by Mr. L. Massopust, the artist of the school.

of a large part of one lobe of the cerebrum (which apparently was not due to postmortem changes following imperfect preservation), marked circulatory deviations, chiefly of the veins, and a number of easily recognizable muscular anomalies, especially of the upper extremity. In fact, the students in the dissecting laboratory claimed "everything was wrong with her."

When the heart[3] was examined and studied, the major portion of the right atrium as well as an extensive area of the aortic arch was found to be bony hard. On laying open the chambers of the heart, it was discovered that not only the entire wall of the right atrium, except where the inferior vena cava and coronary sinus entered, but also the entire interatrial septum was composed of a thick, compact 'osseous' tissue. Moreover, this tissue had extended far up through the anterior or ventral wall of the root and arch of the aorta and had invaded the atrioventricular septa partly surrounding the tricuspid and mitral valves. What was most remarkable about this calcified tissue was its great thickness, in many places measuring from 6 to 8 cm. (2 to 3 inches) across. Even though the ventricular walls, except the atrioventricular septa, were for the most part free from the sclerotic deposit, it is a mystery to the writer how the contractions of the heart could have been sufficiently complete to propel the vascular stream throughout the body. The most notable change occurred in the right atrium. Here the sclerotic layer had become so massive as to have occluded the major part of the atrial chamber, shutting off entirely the superior vena cava, but leaving a lumen approximately as wide as that of the inferior vena cava for the passage of the blood from the latter vein and the coronary sinus to the tricuspid portal. To give actual dimensions, the average thickness of the sclerosed interatrial septum was about 3 cm. (1¼ inches), while that part of the bony wall situated between the end or original mouth of the superior vena cava and the remnant of the atrial cavity was no less than 5.5 cm. (slightly more than 2 inches). The latter relations are indicated in figure 1.

[3] This specimen, numbered M. 344, is in the Museum of Pathology of Marquette Medical School.

The excessive encumbrance to the heart of the sclerosed areas just pointed out had produced a compensatory hypertrophy of the remainder of the heart, although perhaps not to the degree one should expect. The ventricles were somewhat dilated, their muscular walls were correspondingly thick, and the beginning of the aorta was at least twice as wide as in the normal individual. Besides the pathological features already pointed out, the intima

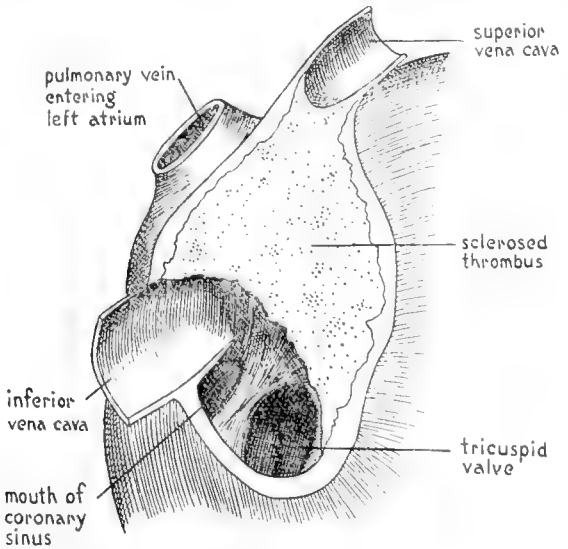

Fig. 1 Semischematic sketch of the right upper portion of the heart, showing one half of the right atrium cut away and illustrating that part of the massive sclerosed thrombus, situated between the orifices of the venae cavae and occluding most of the atrial chamber. Approximately one-half natural size.

or lining of the aortic arch was beset with numerous rough or thin, scaly, bony patches.[4]

A section of the sclerosed wall of the right atrium was prepared for the microscope, which showed definitely, according to Professor McJunkin,[5] that it represented an organized thrombus.

[4] Besides the sclerotic patches on the inner surface of the aorta, there were also little pits or depressions and small, parallel ridges, which I believe are considered indicative of syphilis. In a fixed specimen, however, such depressions and elevations must be taken with reserve.

[5] Prof. F. A. McJunkin, formerly of the Department of Pathology, Marquette School of Medicine, now of the Department of Pathology, Washington University Medical School, St. Louis.

In structure it displayed dense fibrous tissue which had undergone widespread calcification. There were certain peculiarities which suggested syphilitic lesions as a possible initial cause of the thrombus formation. Perhaps it is more likely, however, that the latter began from a secondary infection of some sort, possibly streptococcic in origin, producing a thrombus which arose on the atrial wall itself, or, carried thither from a distant part of the body, became adherent and, gradually growing larger by successive depositions of fibrin, eventually blocked the cavity as demonstrated.

The complete closure of the mouth of the superior vena cava by the atrial thrombus consequently led to extensive modifications in the course and direction of the venous flow from the upper parts of the body to the heart, as illustrated in the diagram, figure 2. These changes may be briefly summarized as follows: 1) All blood returning to the heart from the body above the diaphragm, except that from the coronary veins, was forced to descend to the abdominal cavity, where it discharged into the inferior vena cava. 2) The direction of the blood stream in the azygos system of veins was the exact reverse of that in the normal body. These points are expressed in the diagram (fig. 2) by arrows.

Much of the venous drainage of the head and arm flowed directly into the azygos and hemiazygos veins through the anastomoses of the right and left supreme intercostal and accessory hemiazygos veins with the innominate and vertebral veins. The remainder passed into the superior vena cava, but being unable to enter the right atrium on account of the occlusion of its orifice, it was deflected into the mouth of the azygos vein. From here this blood stream, in conjunction with that coursing through the right supreme intercostal, continued downward in the azygos vein; some of it, however, was turned to the left side through the hemiazygos, thus in direct opposition to the normal course of the flow. All blood passing through the entire extent of the azygos, and most of the blood of the hemiazygos poured via a pair of anastomoses into the interior vena cava immediately below the diaphragm and at the level of the entrance of the

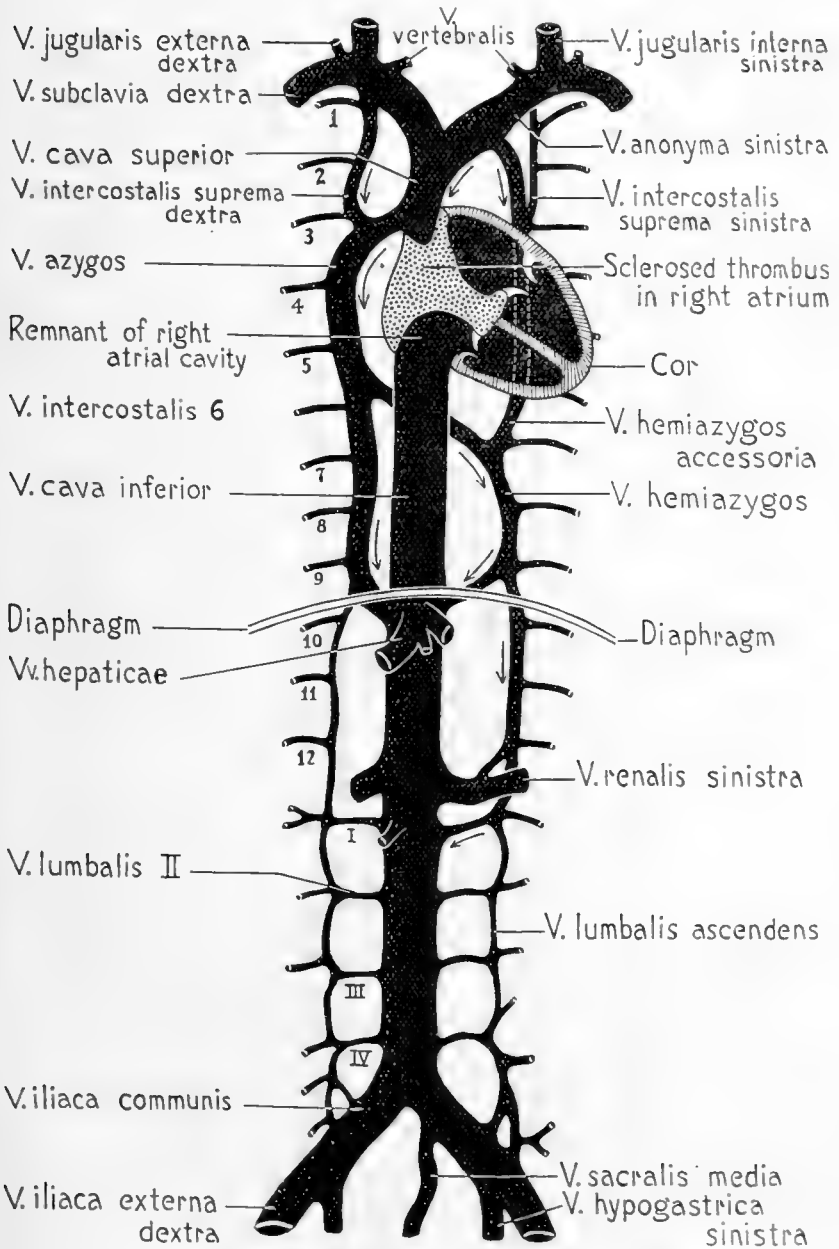

Fig. 2 Diagram showing the closed mouth of the superior vena cava and the resultant modifications in the course and direction of the venous blood stream.

hepatic veins. These anastomoses, which when present in the normal individuals are minute and relatively unimportant, had become very much distended by the demands put upon them. Some of the blood stream of the hemiazygos continued still farther down through the abdominal cavity to empty into the inferior vena cava partly through the left renal vein and partly through the left first lumbar vein.

The valves which are usually assumed to be present in the proximal segment of the azygos vein apparently offered no obstacle to the reversal of the vascular current flowing through it. But such valves do not always exist, and when existent are 'nicht schlussfähig,' according to Spalteholtz (Handatlas der Anatomie, Bd. 2). Valves which are unable to close the lumen perfectly lose their value in determining the direction of the flow when the caliber of the vessel becomes greatly expanded, as occurred in the case of the azygos under consideration.

Besides the deep and important collateral pathways already mentioned, it is possible that much of the superficial haemal drainage of the thoracic wall, which normally discharged into the axillary, subclavian, and innominate veins through the thoracolateral, internal mammary and other smaller veins, was in this instance absorbed by the thoraco-epigastric and the superficial and deep epigastric veins to be carried to the femoral and iliac veins and thence to the inferior vena cava.

Resumen por el autor, Edgar D. Congdon.

Un seno paranasal supernumerario.

La cavidad situada medialmente en la región de la fosa incisiva y los canales del mismo nombre de un adulto, presentaba forma ovoidea y poseía una capacidad de unos 3 centimetros. Su pared ósea no era completa por debajo, mientras que por encima se continuaba con las cavidades nasales mediante los cortos canales incisivos.

La formación de esta cavidad debe atribuirse probablemente a la fusión incompleta de los procesos nasales medio y lateral, así como a la actividad formadora de senos del epitelio respiratorio, que ocupa normalmente el extremo superior de los canales incisivos en vías de desarrollo.

A SUPERNUMERARY PARANASAL SINUS

E. D. CONGDON

Department of Anatomy of the Leland Stanford Junior University Medical School

ONE FIGURE

The cavity shown in the accompanying figure was found by a student while making a sagittal section of an adult head. It is medially placed and extends upward from the region usually occupied by the incisive fossa. It is of a regular ovoid form, 9 mm. in height, 5.5 mm. in anteroposterior diameter, and its width is 8.5 mm. if 2 mm. be allowed for the section removed by the saw. Its interior is lined by a smooth membrane which contained a cyst in the right-hand wall 2 mm. in diameter, whose contents was evidently mucoid in nature. A small deposit of similar appearance lay upon the floor of the cavity.

The bony wall of the space contained above a pair of symmetrically placed short passageways, one of which opened into each nasal cavity, where their location and contents of nerves and blood-vessels identified them as the upper ends of incisive canals. At the palatine end bone was lacking over an area several millimeters in diameter, but the gap was filled upon either side of the saw cut by the membrane lining the cavity and the layers investing the bone of the palate. No communication into nose or mouth was found.

Upon microscopic examination the lining membrane proved to be largely fibrous, but covered on the inner surface by a thin layer of columnar epithelium whose precise structure could not be made out because of maceration.

The frequent presence of abscesses in the alveolar process makes it necessary to consider the likelihood of a pathological origin of the cavity. The neighboring bone and teeth seemed sound. The osseous and membranous walls showed no deteri-

oration other than the maceration of the epithelium, and this was judged to have taken place after death.

The region of the incisive fossae was examined in 128 paired and single maxillae in a search for other cavities similar to the one under discussion. The fossae not infrequently bear a slight resemblance to it, as they may be deeper than wide and somewhat narrowed at their inferior end. They are, of course, much smaller and usually of slightly irregular outline. Two of the series, however, show a distinct resemblance to it in the regularity and roundness of their contour, though they differ in being but slightly constricted below. There is a remote possibility, then, that they also may have contained cavities lined with mucoperiosteum.

The continuity of the bony cavity with the incisive canals in our specimen is an indication that it may have been related to them in development. Leboucq ('81) agrees with the observations of Dursey ('69) and His ('01) whose work was accessible only in references from other writers, that the bony incisive canals surround in the embryo an epithelial tube called the incisive duct which is the result of a reopening of a part of the originally free communication between the spaces above and below the palatine processes. For a time after the median nasal and the palatine portion of the maxillary processes have fused, the duct, though closed, is represented by an epithelial cord continuous with the lining of the nose and mouth. The lumen of the incisive duct which develops in this cord usually disappears a second time permanently before birth.

It seems probable that the cavity here described had its beginning either in the incisive ducts or the passageway from which they are derived. If it arose from one or both ducts, it must have undergone a subsequent enlargement, and since it is lined with columnar epithelium which was probably once continuous with the nasal cavity, it would have claim to classification as a paranasal sinus. This interpretation encounters the difficulty that the connection of the bony cavity with both incisive canals must have been the result of a fusion of their lumina—a process rare in sinus development.

It is more probable that the cavity came into existence as a result of a failure in the meeting of the median nasal and the maxillary processes in this region so that a single large space remained where the lower parts of the incisive ducts usually developed. If this supposition is correct, both a change in the form and an increase in the size of the cavity must have occurred, since a space left between three rounded processes would not have an ovoid form and it could not have equalled in size this cavity of the adult bone. A possible difficulty for either explanation is that the columnar epithelium extends close to the

Right half of sinus at (*a*) exposed by a median sagittal saw cut. × 1

oral surface of the maxilla, while Leboucq found that it gave way in the incisive ducts to the pavement type midway in their course. The exact position of the boundary line is probably not significant, however, since the corresponding transition zone also varies considerably in the nasopharynx.

Works upon palatine malformations and upon the development of the incisive ducts were consulted, including Leboucq ('81), Merkel ('92), Le Double ('96), and His ('01), without finding any reference to a cavity in this region. The studies of the paranasal sinuses by Zuckerkandl ('82), Gruber ('88), Onodi ('07, '08), Underwood ('07), and Shaeffer ('10 and '10 a) do not de-

scribe a sinus here. There is a single record of a similar cavity by Meyer ('13).

In his specimen the position was also medial and the bony wall connected with the osseous enclosures of the nose by short incisive canals, but there was no communication with the oral cavity. The dimensions of the cavity were so considerable (1.6 mm. x 1.35 mm. x 2.2 mm.) that the walls were flattened against various areas of the surrounding compact bone, giving it decidedly the appearance of a sinus. A smooth lining membrane was present. No opening into nose or mouth was found. Professor Meyer concluded that it was a paranasal sinus in a very unusual situation and called attention to Underwood's description ('07) of a sinus similarly placed in the chimpanzee.

The characteristics of the cavity found by Professor Meyer and of the subject of the preceding description are so similar that in the writer's opinion the two must have had a similar origin. The dimensions of the cavity in Professor Meyer's specimen are much greater than possible for an unmodified gap left by the medial nasal and maxillary processes. The probable independence of the two from the nasal cavity at all stages of their developmental history sets them apart from the paranasal sinuses more in appearance than in reality since the evidence points to their origin from a membrane that was once at least in continuity with the nasal lining and similar to it in character.

Resumen por el autor, Clarence Lester Turner.
Colegio Wooster.

Un modelo de cera de un embrión humano en el estado presomítico.

El embrión descrito en el presente trabajo es un embrión humano normal en el estado que precede a la aparición de los somitas. El autor le designa con el nombre de "óvulo de Mateer", en honor del Dr. H. N. Mateer, de Wooster College, quien le obtuvo y conservó.

El embrión mide próximamente un milimetro de longitud, y presenta en buen estado de conservación el disco embrionario, amnios, corion saco vitelino y pedúnculo del cuerpo. Es sumamente notable por estar contenido en un óvulo que también encierra un embrión gemelo en vias de degeneración.

La serie de dibujos, trazados con ayuda de la cámara clara, que acompaña al texto representa los contornos de todos los cortes, que pasan por el disco embrionario, amnios, saco vitelino, alantoides y pedúnculo del cuerpo. Los cortes medían 10 micras de espesor, y los dibujos les representan aumentados 50 diámetros. Si dichos dibujos se aumentan al doble de su tamaño mediante la proyección o la fotografía, pueden trazarse sobre placas de cera de un milímetro de espesor, y el modelo asi obtenido representará una rescontrucción aumentada uniformemente 100 diámetros en las tres dimensiones.

BY THE BIBLIOGRAPHIC SERVICE, NOVEMBER 1

A WAX MODEL OF A PRESOMITE HUMAN EMBRYO

CLARENCE L. TURNER

Biological Laboratory of Wooster College

EIGHTY-ONE FIGURES

INTRODUCTION

The presomite human embryo figured in this article has been fully described by Prof. George L. Streeter, of Johns Hopkins University, in a recent monograph ('19) and the twin formation of the same ovum in a shorter article ('19). He has designated the embryo as the Mateer Embryo after Doctor H. N. Mateer, of Wooster, through whose efforts it was preserved. It is not the purpose of this paper to attempt to repeat any of the work done, but to present a series of drawings representing all the sections through the embryo and the yolk sac. Such a series of drawings makes it possible for every laboratory in which the wax-plate reconstruction process can be carried out to have a model of this embryo for study. The series should also prove of value to classes in embryology, even though the plane of sectioning is very oblique.

The writer is greatly indebted to Doctor Mateer, the owner of the embryo, for a loan of the specimen and for his generous consent in permitting this series of drawings to be published. Several models were constructed, and this series of drawings was prepared in the Biological Laboratory of Wooster College.

THE EMBRYO

The age of the embryo was placed by Doctor Streeter at about seventeen days. The embryonic shield is approximately 1 mm. long and 0.75 mm. wide at its greatest width. Both the embryonic shield and yolk sac are surrounded by a thin layer of mesoderm and the entire vesicle is attached to the chorion by the body stalk. All the structures, with the possible exception of the allantois, are apparently quite normal.

A. Embryonic shield

The embryonic shield is oval in shape, but narrows markedly and bends ventrally in its posterior third. The oval portion is not marked by any uneveness, but the narrow posterior third is traversed longitudinally by a shallow primitive groove. At the periphery of the shield the ectoderm is continuous, becoming thin and folding over dorsally to form the amnion.

B. Amnion and amniotic cavity

The line of demarkation between the embryo and the amnion is difficult to distinguish in many of the sections, but the amniotic ectoderm is very thin and is overlaid by mesoderm which binds it loosely to the overlying chorion. Owing to the oblique plane of sectioning, an exaggerated impression of the depth of the amniotic cavity is gained from figure 16. The cavity appears in the reconstruction as a mere cleft except at the extreme posterior end where it comes into contact with the body stalk.

C. Body stalk and allantois

The body stalk, occurring at the posterior end of the yolk sac, is a fairly compact mass of mesoderm attaching the entire vesicle to the chorion (fig. 22, BD.S.). A few loose strands of mesoderm extend from the body stalk to the chorion, and at one point near the chorion the body stalk is interrupted by a large cavity. Some primitive blood-vessels are found also in the body stalk, but no attempt has been made to represent them in the drawings.

The allantois at its proximal end appears as an evagination of the yolk entoderm and within the next few sections becomes a compact round column of cells. The proximal portion of the allantois terminates abruptly and no trace of it can be found for a few sections after which it reappears as a detached segment. In the reconstruction this detached segment shows a marked constriction.

D. Yolk sac

The yolk sac is much flattened dorsoventrally although its probable normal shape was nearly spherical. As the chorionic vesicle is also flattened in the same direction, it seems likely that both chorion and yolk sac were flattened by their own weight prior to fixing. On the ventral and posterior surfaces of the yolk sac are numerous blood-islands.

E. Chorion

There are two layers present in the chorion, an inner mesodermal layer, which is loose in texture but distinct, and an outer and more compact ectodermal layer. Chorionic villi are attached to the chorionic membrane at intervals. The same layers appear in the villi that are present in the chorionic membrane, the ventral mass consisting of the mesodermal element and the outer layer a covering of ectoderm. A syncytial and an epithelial layer may be distinguished in the ectoderm, but they have not been shown in the figures.

F. Twin vesicle

In figure 30 there occur between the large embryo and the chorionic membrane two smaller vesicles which prove to be parts of a second smaller embryo evidently undergoing degeneration. In the larger of these two smaller vesicles a sphere of ectoderm surrounded by mesoderm can be distinguished. The ectodermal sphere enclosing an amniotic cavity is thickened on one side to form the embryonic ectoderm, while the remainder forms an amnion. The second and smaller vesicle is apparently the degenerating yolk sac of the small twin embryo. Both vesicles are loosely bound to the body stalk and to the chorion by strands of mesoderm.

CONSTRUCTION OF MODEL

The plane of sectioning is represented by the line AB. The sections were made 10 μ thick. A few sections were irregular in thickness or were lost, a number have been twisted and a few

broken into fragments. However, by taking the perfect sections as guides, the imperfect sections may be made to conform to the shape as indicated in the perfect sections. With these few exceptions, the sections are in good condition. All the drawings in this series were made with a camera lucida and all the imperfections are figured as they occur in the sections.

A. Irregularities

The more outstanding irregularities are listed here with the expectation that they will prove useful for corrections during the construction of a model. The irregularities were checked by making a duplicate set of drawings with carbon paper, using one set for the construction of the model and carefully marking the necessary alterations on the other set of drawings.

Section 2 to section 9. The amnion on the right side has collapsed or has been pushed in.

Section 3 to section 15. There is a shrinkage of the mesoderm on the left side of the embryo between the embryonic disk and the yolk sac.

Section 5 to section 17. An indentation in the right side of the yolk sac and the overlying mesoderm is evidently an artifact.

Section 3 to section 20. The embryonic disk is cracked in most of these sections and in a few the parts have suffered a slight displacement.

Section 14 and section 15. Two sections have apparently been lost between these two.

Section 17. This one is 40 μ thick instead of 10 μ thick.

Section 16 and section 17. The left half of the embryonic disk is bent ventrally so as to be out of adjustment.

Section 23. There is a lateral compression in this section which distorts it somewhat. The foregoing section may be taken as a guide.

Section 24. As in section 23.

Section 30. The yolk sac membrane and the overlying mesoderm are shrunken and distorted.

Section 32 and section 33. These are somewhat broken and

the pieces displaced, but the general boundaries of the sections are still evident.

Section 34. The ventral half of the yolk sac has been dislocated toward the left.

Section 35. There are two slight breaks in the walls of the yolk sac.

Section 37. This section is 20 μ thick.

Section 40. The walls of the yolk sac are broken at the ventral point and are shifted toward the left in the ventral half.

Section 42. The sides of this section are somewhat compressed.

Section 46. This section is bent toward the left in its ventral half.

Section 47. The sides of this section are slightly compressed and the lower half is dislocated toward the left.

Section 48 and section 49. Several sections are missing between these two.

Section 50 to section 81. There are many slight irregularities in the shape of the yolk sac, but the shape may be made out by using the following sections as of normal shape: sections 58, 61, 63, 68, and 73.

B. Magnification

The sections have been cut 10 μ in thickness so that a magnification of 100 would make the wax sheets 1 mm. in thickness. In the illustrations in this article a magnification of 100 has been used, but the drawings have been reduced one-half for publication. It is suggested that they be stepped up to their original size (twice as large as represented here) when wax sheets of a thickness of 1 mm. may be used.

C. Modeling

A model such as the one illustrated in plate 1 may be constructed by the usual Borns' wax-plate method. A more substantial model which may be handled by students may be constructed by substituting blotting-paper soaked in equal parts of beeswax and soft paraffin for wax sheets.

The structures which serve best as guide lines in building the model are the body stalk and the allantois. The posterior margin of the amniotic cavity can also be used to advantage.

THE ANATOMICAL RECORD, VOL. 20, NO. 1,
DECEMBER, 1920

Resumen por los autores, George S. Huntington y
Charles F. W. McClure,
Columbia University y Princeton University.

El desarrollo de las venas en el gato doméstico (Felis domestica), con especial mención de: 1) la participación de las venas supracardinales en el desarrollo de la postcava y vena azigos, y 2) la interpretación de las condiciones de variación de la postcava y sus tributarios encontradas en el adulto.

Esta investigación fué comenzada en 1905 con el propósito de determinar el plan venoso ontogénico normal que serviría como base para explicar las variaciones observadas en el gato adulto como resultado de un desarrollo atípico de las venas. El trabajo vá ilustrado con doce figuras en colores, basadas en reconstrucciones en cera, y dichas figuras servirán también para explicar las condiciones observadas por los autores en el hombre. Algunos de los puntos mas importantes tratados por los autores son los siguientes: 1. La división postrenal de la vena postcava se deriva exclusivamente de una parte de las venas subcardinales, partir endo del lado derecho de lo que los autores han llamado el cuello renal, y de las venas supracardinales. Ninguna parte se deriva principalmente de las venas postcardinales. 2. Las venas azigos se derivan de las supracardinales. 3. Una nueva interpretación sobre el desarrollo de las venas sexuales. 4. Un esquema compuesto que presenta combinados todos los trayectos venosos que pueden aparecer durante la ontogenia. Por medio de este esquema se pueden interpretar los diecisiete tipos en los cuales pueden clasificarse las variaciones de la postcava encontradas en el gato y en el hombre.

Translation by José F. Nonidez

AND

CHARLES F. W. McCLURE
Princeton University

TWELVE FIGURES (IN COLORS)

This investigation was begun in 1905. In the preceding years we had found that the variations or atypical conditions of the venous system observed by Darrach,[1] McClure[2] and others in the adult cat could not all be explained on the basis of the existing knowledge of the development of the veins. We therefore determined to study in detail the normal ontogenetic plan of the veins in the cat, with the hope that we might be able to interpret correctly the variant conditions of the venous system which arose as the result of atypical development of the veins.[3]

We have recently extended our observations to a study of the development of the veins in man, the pig and the rat, and while

[3] Huntington, G. S., and McClure, C. F. W. 1907 The Development of the Postcava and Tributaries in the Domestic Cat. Proc. Amer. Ass. Anat., Amer. Jour. Anat., Vol. 6.

it has been observed that important generic differences exist in the pig and the rat, the development of the veins in man has been found to resemble more closely that observed in the cat.[4]

Although our investigation has been completed, it may be some time before the detailed publication is ready for the press. We have therefore deemed it advisable to publish a preliminary summary of our work in the form of a series of diagrams which illustrate the normal ontogenetic plan followed by the veins, with especial reference, however, to the share taken by the supracardinal system of veins in the development of the azygos vein and of the postrenal division of the postcava in the cat. A brief summary is also given of the potential postcaval variants in the adult cat and man. An explanation of these variant conditions is based on a composite diagram (fig. 12) combining all of the venous pathways which may arise during ontogeny and which are potentially capable of being retained in the adult in atypical individuals.

The diagrams which we present are based on a large series of wax reconstructions made after the method of Born, of cat embryos ranging between 5 and 45 millimeters in length. They represent a series of critical ontogenetic stages leading from the early primitive venous groundplan common to all vertebrates (fig. 1), up to the conditions obtaining in the adult cat.

In constructing these diagrams it was deemed desirable to include all of the main axial venous channels of the body other than those investigated by us, and we fully appreciate and acknowledge that the previous contributions of other investigators, especially those of Rathke,[5] Hochstetter[6] and F. T. Lewis,[7] have made this possible.

[4] Huntington, G. S. and McClure, C. F. W. 1920. A series of diagrams explanatory of the development of the postcava in the cat, with especial reference to the share taken by the supracardinal system of veins. Proc. Amer. Ass. Anat., Anat. Rec., Vol. 18.

[5] Rathke, H. 1838. Ueber den Bau und Entwicklung des Venensystems der Wirbeltiere. Dritte Bericht über das Naturwissenschaftliche Seminar zu Königsberg. Idem. 1832. Abhandlungen zur Bildungs-und Entwicklungsgeschichte des Menschen und der Thiere. Leipzig, T. I.

The uniform color scheme shown in the figures makes it easy to follow the transformations of the embryonic venous system through the different stages of its development. Only a brief account of each critical stage will be given in the present paper, while a more detailed description will be reserved for a later publication in which the actual reconstructions will be demonstrated on which our observations have been based.

FIG. 1. CARDINO-SUBCARDINAL STAGE.

This stage of development may be regarded as representing a common groundplan of the vertebrate embryonic venous system. It forms the starting point which is succeeded by a series of modifications gradually leading up to the conditions observed in the adult. In some cases these modifications are brought about by the persistence or atrophy of certain of its component vessels, while in others, modifications arise by the addition of newly-formed vessels to the primary groundplan. The diagrams we present illustrate these modifications of the embryonic groundplan as observed in the embryo of the cat.

The principal vessels of the embryonic venous groundplan consist of three pairs of essentially bilateral symmetrical veins, viz.: the precardinal (*Prc.*) and postcardinal (*Pc.*) veins which open in common into the sinus venosus through the ducts of Cuvier (*D.C.*) and the subcardinal (*Subc.*) veins. The postcardinal veins lie dorsal to the mesonephroi, while the subcardinals lie ventro-medial to the same. Anastomoses between the postcardinal and subcardinal veins are present and intersubcardinal anastomoses are met with caudal to the origin from the aorta of the omphalomesenteric artery.

The sex veins from the gonads (*G*) open into the subcardinal veins at this stage. The veins of the liver drain for the most part directly into the sinus venosus through the V. hepatica communis (*V.H.C.*) and no connection between the liver circulation and the right subcardinal vein has as yet been formed.

The blood collected from the body-walls and mesonephroi by the postcardinals, as well as that carried by the subcardinal veins, is returned to the heart through the ducts of Cuvier (*D.C.*) in common with that brought from the head region and anterior limb-buds by the precardinal veins.

FIG. 2. ESTABLISHMENT OF THE PARS HEPATICA AND PARS SUBCARDINALIS OF THE POSTCAVA, CONSTITUTING THE PRERENAL DIVISION OF THE POSTCAVA IN THE ADULT.

The significant features of this stage of development, are the establishment of the prerenal division of the adult postcava, and the beginning replacement of an originally bilaterally symmetrical by a subsequent asymmetrical plan of axial venous organization.

As shown by F. T. Lewis, the prerenal division of the postcava is formed by the establishment of a communication between the veins of the liver and the right subcardinal vein. The point at which this communication is established with the right subcardinal has been previously designated by one of the writers[8] as the hepato-subcardinal junction (*Hep.Subc.Jct.*).

The portion of the prerenal division of the postcava which lies cranial to the hepato-subcardinal junction may be termed the *pars hepatica* (*P.Hep.*). It is formed *in situ* by a rearrangement and transformation of vascular channels already formed, viz., by the V. hepatica communis, the hepatic sinusoids and by the vascular area formed within the caval mesentery.

The portion of the prerenal division of the postcava which lies caudal to the hepato-subcardinal junction is known as the *pars subcardinalis* (*P.Subc.*), as it is formed largely by a portion of the right subcardinal vein. Slightly caudal to the origin of the omphalomesenteric artery from the aorta, the pars subcardinalis establishes a wide communication with the left subcardinal, through an intersubcardinal anastomosis (*Int.Subc.Anast.*) and also one with each postcardinal, by the enlargement of one of the anastomoses that exist at this level between the intersubcardinal anastomosis and the postcardinal veins (subcardino-postcardinal anastomoses, *Subc.Pc.Anast.* (fig. 12)).

As the result of these modifications of the early embryonic groundplan, the blood from the region of the body which lies caudal to the intersubcardinal anastomosis (body-walls and mesonephroi) is now, for the most part, directed from the postcardinal (*Pc.2*), on both sides of the body, through the subcardino-post-

[8] McClure, C. F. W. 1906 A contribution to the anatomy and development of the venous system of Didelphys marsupials (L.). Amer. Jour. Anat., Vol. 5, p. 171.

cardinal anastomosis to the prerenal division of the postcava. Also, correlated with these changes, the postcardinals (*Pc.2*), caudal to the intersubcardinal anastomosis, become greatly enlarged, while the segments cranial (*Pc. 1*) to this anastomosis become reduced and return blood from the body-walls of the thoracic region and from the cranial end of the mesonephroi directly to the heart by the ducts of Cuvier (*D.C.*).

The sex veins still open into the subcardinal veins. Anastomoses are also still present between the subcardinal and postcardinal veins, caudal to the intersubcardinal anastomosis, which form part of the mesonephroic circulation. In the region cranial to the intersubcardinal anastomosis, however, the subcardinals soon become associated with the anlagen of the adrenal bodies forming the main venous drainage line of these organs which is retained throughout subsequent stages of development.

FIG. 3. FURTHER TRANSFORMATIONS OF THE POSTCARDINAL AND SUBCARDINAL VEINS WHICH ARE ASSOCIATED LARGELY WITH THE GROWTH OF THE MESONEPHROS.

SEPARATION OF THE POSTCARDINAL VEINS INTO A THORACIC AND LUMBAR DIVISION.

The originally continuous postcardinals have now become divided into a cranial or thoracic (*Pc.1*), and into a caudal or lumbar (*Pc.2*) pair of veins. The former collect the blood chiefly from the body-walls of the thorax and from the anterior portion of the mesonephroi, while the latter drain the more caudal regions of the body.

The lumbar division of the postcardinal (*Pc.2*), on each side of the body, now encircles the relatively large mesonephros, both dorsally and medially, so that in reconstructions of the veins at this stage each mesonephros appears to be arched over by or to lie within a great venous basket or trough formed by the postcardinal vein and its subcardinal anastomoses.

The permanent kidneys (*K*) have migrated craniad from their earlier position ventral to the umbilical arteries and now occupy a position dorsal to the lumbar postcardinals (*Pc.2*).

Cranial to the intersubcardinal anastomosis (*Int.Subc.Anast.*) the subcardinal veins, except that portion of the vein of the right

side which forms the pars subcardinalis of the postcava (*P.Subc.*), have become still more closely associated with the adrenal organs so that from now on, we may speak of these veins as the adrenal veins (*Adr.*). Caudal to the intersubcardinal anastomosis the subcardinal veins have lost their original continuity so that the sex veins, of subcardinal origin, now drain directly into the postcardinals (*Pc.2*), as well as into the intersubcardinal anastomosis. The significance of this observation lies in the circumstance that the sex veins at this time are exclusively of subcardinal origin, a condition which is retained in the adult of lower vertebrates, up to and including birds.

FIG. 4. THE ESTABLISHMENT OF THE SUPRACARDINAL SYSTEM OF VEINS AND THE RENAL COLLAR.

A bilateral and originally symmetrical venous channel develops dorso-medial to the primitive postcardinal and dorso-lateral to the aorta, into which the somatic postcardinal tributaries secondarily drain. This secondary venous channel forms what we have termed the *Supracardinal System of Veins* (*Sprc.*). It extends, from the level at which the posterior limb veins unite with the postcardinals, to a point craniad where it joins that portion of the postcardinals (*Pc.1*) which alone persists to form the cranial end of the adult azygos (*Az.*) veins. Between these levels the supracardinal veins come to enter into the definite organization of both the adult postcava in its postrenal division and of the azygos in its lumbar and part of its thoracic segments, entirely replacing in these districts the primitive postcardinal veins.

"It is important to note that the supracardinal veins are not in any sense merely synonyms for the dorsal limb of the periureteric ring described by Hochstetter and others, but comprise a continuous morphologically uniform system of longitudinal venous channels which contribute to the establishment of the adult condition in both the postcaval and azygos areas."[9]

The beginning of the establishment of the supracardinal system of veins takes place at a relatively early stage of development, and its cranial extension into the thoracic region is evidence that its appearance is not primarily associated with the cranial migration of the permanent kidneys. Frequent anastomoses occur

[9] Loc. cit., footnote 3.

between the postcardinals and supracardinals at an early stage of development and, at this time, the anastomoses between the right and left supracardinal veins (intersupracardinal anastomoses), as shown in figure 4, have not yet been formed.

The early anastomoses between the supracardinal and postcardinal veins soon undergo atrophy and disappear. A large single anastomosis (fig. 4, *R.Col.*), at about the level of the intersubcardinal anastomosis, is retained, however, on each side of the body, which permits blood collected by the supracardinals in the lumbar region to reach the heart by way of the prerenal division of the postcava. This anastomosis we have designated as the subcardino-supracardinal anastomosis (*R.Col.*, fig. 4), since, in the later stages, it appears to connect the subcardino-postcardinal anastomosis with the supracardinal vein.

The blood collected by the supracardinal veins which is not directed to the prerenal segment of the postcava through the subcardino-supracardinal anastomosis, reaches the heart by way of the ducts of Cuvier (*D.C.*).

The formation of this subcardino-supracardinal anastomosis, at about the level of the intersubcardinal anastomosis, establishes the presence of a circum-aortic venous ring at this point which we have designated as the *Renal Collar*.

In order to appreciate the topographical relations of the renal collar to the main venous channels and the aorta, the reader is referred to fig. 12, a diagram based largely on the reconstruction of a 16 millimeter embryo of the cat. As clearly shown here, the renal collar is formed by the pars subcardinalis of the postcava (*P.Subc.*), the intersubcardinal anastomosis (*Int.Subc. Anast.*), the right and left subcardino-postcardinal anastomoses (*Subc.Pc.-Anast.*), the right and left subcardino-supracardinal anastomoses (*Subc.Spre.Anast.*), the right and left supracardinals (*B* and *C*) and the anastomoses between the supracardinals dorsal to the aorta at this point, at which level the renal veins (*R.V.*) enter the collar.

The sex veins (fig. 4) still join the postcardinals and, in some cases, as shown in fig. 3, they may also open into the intersubcardinal anastomosis, a condition which is occasionally retained in the adult when multiple sex veins are present.

FIGURE 5. PROGRESSIVE DEVELOPMENT OF THE BILATERAL, SYMMETRICAL SYSTEM OF SUPRACARDINAL VEINS.

SEPARATION OF THE SUPRACARDINALS INTO AN AZYGOS AND LUMBAR DIVISION.

COMPLETION OF THE CRANIAL MIGRATION OF THE PERMANENT KIDNEYS, THE DEVELOPMENT OF THE RENAL VEINS AND THE ESTABLISHMENT OF THE PERIURETERIC VENOUS RINGS.

The supracardinal veins (*Sprc.*) at first undergo a progressive development during which their bilateral symmetry is retained for a considerable period of time. They soon separate, however, into a cranial or azygos and into a caudal or lumbar pair of veins, from which the azygos veins and a segment of the postrenal division of the adult posteava are, respectively, derived.

The bilateral symmetrical pair of supracardinals in the lumbar region anastomose freely with each other dorsal to the aorta and become greatly increased in size. Blood which they receive from the body-walls through four pairs of dorsal tributaries, and that received by them from the external (*E.Il.*) and internal iliac (*I.Il*) veins, now reaches the prerenal segment of the posteava exclusively through the right and left subcardino-supracardinal anastomoses (lateral portion of renal collar, *R.Col.* fig. 5), which have become correspondingly enlarged.

Blood collected by the supracardinals in the thoracic region (azygos veins), chiefly from the body-walls, is returned to the heart through the right and left ducts of Cuvier (*D.C.*), in common with that collected from the head region and anterior limbs by the precardinal veins.

The permanent kidneys (*K*) have completed their migration craniad, and the hilus of each kidney now lies at about the level of the renal collar (fig. 12). After the migration of the kidneys has been completed, the permanent renal veins (*R.V.*) are formed. These consist at first of a right and left pair of renal veins which extend between the hilus of each kidney and the lateral portion of the renal collar (*R.V.*, fig. 12).

The relation of the renal veins to the lateral portion of the renal collar (subcardino-supracardinal anastomosis) is shown in figs. 8 and 9 which are lateral views of the right side of actual recon-

structions of the veins of cat embryos measuring, respectively, 16 and 25 mm. in length. Near the hilus of the kidney, each renal vein divides into two branches (fig. 5) and, in some cases, the bifurcation may even extend back to the renal collar.

The primitive postcardinal veins (*Pc.2*, fig. 5) still retain their bilateral symmetry. They unite caudally with the supracardinals in the lumbar region and, in addition to blood received from the mesonephroi and gonads, they also receive, in part, that collected by the external (*E.Il.*) and internal iliac (*I.Il.*) veins. Craniad, the postcardinals (*Pc.2*) also unite with the supracardinals (*Sprc.*) through the subcardino-supracardinal anastomosis (lateral portion of renal collar, *R.Col.*, fig. 5) so that the blood collected by the supracardinals and postcardinals in the lumbar region is then conveyed to the prerenal division of the postcava, on each side of the body, through the original subcardino-postcardinal anastomoses (*Subc.Pc.Anast.*, fig. 12) which constitute the ventral portions of the renal collar. (Compare figs. 5 and 12.)

As the result of this cranial and caudal union in the lumbar region between the postcardinal and supracardinal veins, a venous ring has been established on each side of the body, through which the ureter (*Ur.*) passes. This periureteric venous ring is bounded cranially by the caudal border of the subcardino-supracardinal anastomosis (*R.Col.*, figs. 5 and 8 and *Subc.Sprc.Anast.*, fig. 12), dorsally by the supracardinal and ventrally by the postcardinal vein. In the region of the renal collar the ureter (*Ur.*) lies dorsal to the postcardinal (*Pc.2*) and sex vein, while further caudad it passes ventral to the postcardinal vein.

Final Transformations of the Veins (Figure 6) Which Lead Up to the Conditions Found in the Adult Cat (Figure 7).

The primary bilaterally symmetrical plan of the supracardinal veins in the lumbar region (fig. 5, *Sprc.*) is soon replaced by an asymmetrical one (fig. 6). This change is initiated by a reduction of the left side of the circum-aortic venous ring, involving its supracardinal component and of the portion labelled *R.Col.*, fig. 6, while the corresponding channels of the right side enlarge. This

change is finally followed by the complete atrophy of the left side of the renal collar, or strictly speaking, of the subcardino-supracardinal anastomosis of the left side.

In consequence of this change, the blood collected by the left supracardinal vein is therefore directed toward the right supracardinal through the intersupracardinal anastomoses and, together with the blood collected by the right supracardinal, now reaches the prerenal division of the postcava by way of the right side of the renal collar. Fig. 6 represents a stage in which the left side of the renal collar is undergoing atrophy, while in fig. 7, the left side of the collar has completely disappeared.

While it may be said that the right supracardinal vein is chiefly concerned in the formation of a portion of the postrenal division of the postcava, the supracardinal vein of the left side is also involved. The left supracardinal (fig. 6) does not, as one might suppose, undergo complete atrophy *in situ*, but rather is drawn into or fuses with the vein of the right side, at least in the caudal half of its extent. This portion of the postcava derived from the supracardinals (pars supracardinalis, fig. 7) may therefore be regarded as being formed largely through a fusion of both supracardinal veins, and not from a single vein on the right side, as is usually described to be the case, although the latter furnishes the major contribution.

It has been stated above that after the complete atrophy of the left side of the renal collar, all of the blood collected by the supracardinals in the lumbar region reaches the prerenal division of the postcava through the right side of the renal collar. One of the most interesting observations we may have made regarding the development of the veins in the cat, is that the right side of the renal collar typically enters directly into the formation of a definite portion of the postrenal division of the postcava, which we have designated the *pars renalis* (*P.Ren.*) of the postcava, on account of its relation to the entrance of the renal veins (*R.V.*, fig. 7). The manner in which this is brought about can best be illustrated by a series of actual reconstructions of the veins which show the relations that the right side of the renal collar bears to

the prerenal division of the postcava and to the supracardinal and postcardinal veins. The reconstructions referred to are represented by figs. 8, 9, 10 and 11 which are lateral views of the veins of the right side of cat embryos measuring 16, 25, 29 and 45 mm., respectively, in length.

In the 16 mm. embryo (fig. 8) it is seen that the right periureteric venous ring is still complete and that blood from the caudal region of the body can reach the prerenal division of the postcava by two routes, viz., by way of the right postcardinal vein (*Pc.2*), into which the sex veins open, and by way of the right supracardinal vein and right side of the renal collar. This latter route is the permanent one typically retained in the adult and *constitutes the postrenal division of the postcava*. In the 16 mm. embryo, from which this figure was drawn, the left side of the renal collar is also intact, so that blood from the left side of the body can also reach the prerenal segment of the postcava through a corresponding set of veins (fig. 5).

In the 25 mm. embryo (fig. 9) both postcardinal veins (*Pc.2*) have given up their caudal connection with the external and internal iliac veins and the left side of the renal collar has also completely disappeared, so that blood from the hind limbs and lumbar region of the body, now reaches the prerenal division of the postcava solely through the fused supracardinals and the right side of the renal collar. The right postcardinal vein opens into the ventro-caudal border of the renal collar (figs. 9 and 12) and returns blood to the prerenal segment of the postcava, which it receives exclusively from the right mesonephros and from the right gonad through the sex vein.

The venous arch formed by the fused supracardinals and right side of the renal collar, in figs. 8 and 9, is a marked and constant character of these veins in the earlier stages, a condition, however, which is later changed. This change consists of a straightening out of the arch formed by the supracardinals, and of an *actual elongation, in a cranio-caudal direction, of the right side of the renal collar*. Fig. 10, of a 29 mm. embryo, shows the renal collar in the process of elongation, while in fig. 11, of a 45 mm. embryo, the elongation has been completed and the collar assumed the

condition permanently retained in the adult. As a result of this elongation, the point at which the right postcardinal (*Pc.2*) opens into the renal collar becomes gradually shifted caudad, so that the right postcardinal finally opens into the postcava (renal collar) somewhat caudal to the points of origin of the right renal veins (*R.V.*, fig. 11).

The blood from the right gonad reaches the right postcardinal through the sex vein of subcardinal derivation. After the complete degeneration of the right mesonephros, the original drainage line of the right postcardinal is occupied exclusively by that of the right sex vein (figs. 8, 9,10, 11 and 7). The original point of connection of the right postcardinal with the renal collar, although shifted caudad, is therefore retained in the adult as the point at which the postcava is joined by the right sex vein. This point, as we have seen, is the ventro-caudal border of the right embryonic renal collar. In figs. 6 and 7, the elongation of the right side of the renal collar is represented as having taken place.

Considerable variation has been found to exist in the adult cat, as regards the relation of the points at which the right sex and the right renal veins open into the postcava. This variation can undoubtedly be explained, in some cases, at least, on the ground that the extent to which the right side of the renal collar elongates in a cranio-caudal direction may differ in individual cases. The opening of the right sex vein into the postcava, caudal to that of the right renal vein is, however, now easily explained, on the basis of an elongation of the right side of the renal collar. Furthermore, it is plainly evident that the *right postcardinal vein does not, in the slightest degree, as hitherto supposed, enter into the formation of the postrenal division of the postcava which, as we have seen, is formed by the supracardinal veins (P. Sprc.) and by the right side of the renal collar* (*P. Ren.*, fig. 7).

As far as the postcava and its tributaries are concerned, there still remain to be considered further changes regarding the right and left renal veins and the sex vein of the left side.

It has been stated above that after the migration of the kidneys has been completed, the permanent renal veins are formed. These consist at first of a right and left pair of renal veins which

extend between the hilus of each kidney and the lateral portion of the renal collar (*Subc. Sprc. Anast.*, fig. 12).

The condition which obtains on the right side of the body in the adult, appears to be brought about by the persistance of the more ventral of the two embryonic renal veins and the complete atrophy of the other (fig. 7). This single right renal vein then retains its connection with the pars renalis of the postcava which is formed from the right side of the renal collar (fig. 7).

The relations of the postcardinal vein, into which the sex vein opens, and of the two embryonic renal veins to the renal collar are originally the same on both sides of the body (figs. 5 and 12). When the left side of the renal collar (subcardino-supracardinal anastomosis) atrophies, however, the more ventral of the two embryonic renal veins and the left postcardinal vein continue to retain their connection with the left subcardino-postcardinal anastomosis. The result is that the latter, together with the more ventral of the two embryonic renal veins, then forms the left renal vein of the adult, while the left postcardinal vein, after the complete degeneration of the mesonephros, serves as the pathway through which the left sex vein opens into the left renal vein (compare figs. 6 and 7).

On the basis of their development, the presence in the adult cat of two, three or even four renal veins on the same side of the body is now not difficult to explain. When more than two renal veins are present this condition is undoubtedly related to the extent to which the bifurcation of the original embryonic renal veins is involved.

It has long been erroneously stated in text-books of embryology that the postcardinal veins in the thoracic region give rise to the azygos veins. The history of the development of the azygos veins in the cat is illustrated in figures 3 to 7, inclusive, in which it is shown that they are derived chiefly from the supracardinals and that in the adult cat only the proximal end of the right azygos near the duct of Cuvier, is derived from the postcardinal vein (*Pc.1*).

As stated at the beginning of this paper the chief object of our investigation was to establish the normal ontogenetic plan

of the veins in the cat, with the hope that we might be able to interpret correctly the variant conditions of the venous system which arose as the result of atypical development of the veins.[10] On the basis of this investigation we have therefore constructed a composite diagram (fig. 12) of the embryonic veins of the cat which make their appearance, at one time or another, during the course of ontogeny.

We have already shown in the preceding pages how some of these embryonic veins function only temporarily and then disappear, while others persist and are carried into the adult stage. When we meet with a venous variant in the adult it is therefore due, in the majority of cases, to the occurrence and persistence of some modification of the ontogenetic plan ordinarily followed by the veins, which is carried into the adult. It is also evident when such atypical conditions arise, that their explanation lies in the determination of the normal potential embryonic pathways which may have been concerned. Also, if our composite diagram of the embryonic veins is correct, we should not only be able to interpret the atypical conditions already found, but should also be able to predict those which are potentially capable of occurring in the adult cat.

On the basis of this composite ontogenetic plan of the veins we have been able to classify under 17 main *Types* the variant conditions of the postcava which may occur in the adult cat. We have also found that all of the postcaval variations thus far observed in man by other investigators, as well as by ourselves, can be classed under these same types.

If we return to the composite diagram (fig. 12) we see that the embryonic veins which typically enter into the formation of the adult postcava are the right supracardinal (*B*), the right subcardino-supracardinal anastomosis (*Subc.Sprc.Anast.*), the right subcardino-postcardinal anastomosis (*Subc.Pc.Anast.*), the intersubcardinal anastomosis (*Int.Subc.Anast.*), the pars subcardinalis (*P.Subc.*) and the pars hepatica (*P.Hep.*) of the postcava.

[10] Huntington, G. S. and McClure, C. F. W. 1907 The interpretation of variations of the postcava and tributaries of the adult cat, based on their development. Proc. Amer. Ass. Anat., Amer. Jour. Anat., Vol. 6.

On the other hand, it is plain that the persistence in the adult of the left supracardinal (*C*), or of the right postcardinal (*A*), or left postcardinal (*D*), either singly, in combination with one another, or with the right supracardinal vein (*B*) to form the postrenal division of the postcava, would constitute an atypical condition of the veins. In addition to the typical condition of the postcava, mentioned above, which we may speak of as *Type B*, there are therefore 14 other combinations potentially possible between the right and left postcardinals and the right and left supracardinals in the lumbar region, any one of which may persist in the adult and constitute a variant condition of the postrenal division of the postcava.

These *Types* are as follows (fig. 12):

1. *Type A*, persistence of right postcardinal (*A*) vein.

2. Type *AB*, persistence of right postcardinal (*A*) and right supracardinal (*B*) veins. Right periureteric venous ring.

3. *Type ABC*, persistence of right postcardinal (*A*), right supracardinal (*B*) and left supracardinal (*C*) veins. Right periureteric venous ring.

4. *Type ABCD*, persistence of right postcardinal (*A*), right supracardinal (*B*), left supracardinal (*C*) and left postcardinal (*D*) veins. Right and left periureteric venous rings.

5. *Type ABD*, persistence of right postcardinal (*A*), right supracardinal (*B*) and left postcardinal (*D*) veins. Right periureteric venous ring.

6. *Type AC*, persistence of right postcardinal (*A*) and left supracardinal (*C*) veins.

7. *Type ACD*, persistence of right postcardinal (*A*), left supracardinal (*C*) and left postcardinal (*D*) veins. Left periureteric venous ring.

8. *Type AD*, persistence of right (*A*) and left postcardinal (*D*) veins.

9. *Type BC*, persistence of right (*B*) and left supracardinal (*C*) veins.

10. *Type BCD*, persistence of right (*B*) and left supracardinal (*C*) and left postcardinal (*D*) veins. Left periureteric venous ring.

11. *Type BD*, persistence of right supracardinal (*B*) and left postcardinal (*D*) veins.

12. *Type C*, persistence of left supracardinal (*C*) vein.

13. *Type CD*, persistence of left supracardinal (*C*) and left postcardinal (*D*) veins. Left periureteric venous ring.

14. *Type D*, persistence of left postcardinal (*D*) vein.

With the exception of *Types ABD*, *ABCD* and *BCD*, all of the above-mentioned Types have been observed by us or by others, either in the adult cat or man. Type *ABCD*, however, has been figured by Hochstetter[11] as occurring in Erinaceus europaeus.

It is interesting to note in *Types A*, *D* and *AD* (fig. 12), that the lateral portion of the renal collar (subcardino-supracardinal anatomosis, *Subc. Sprc.Anast.*) does not enter into the formation of the postrenal division of the postcava, and, furthermore that an atypical condition invariably results whenever the postcardinal veins persist in the adult. This further emphasizes the fact, already mentioned, that the right postcardinal vein does not, in the slightest degree, typically enter into the formation of the postcava in the adult cat.

Three other types of variations of the postcava are met with which may result from atypical development of the embryonic veins. These are as follows (fig. 12):

15. *Absence of the Prerenal Division of the Postcava and Substitution for the Latter in the Thoracic Region, of the Right or Left or of Both of the Supracardinal (azygos) Veins, as the Direct Cranial Continuation of the Postrenal Division of the Postcava.*

The postrenal division of the postcava, in such cases, is usually formed by the right (*Type B*), the left (*Type C*) or by both of the supracardinal veins (*Type BC*). It would be quite possible, however, for the postcardinals (*A* and *D*) in the lumbar region also to persist in place of, or in combination with the supracardinal veins (*B* and *C*) but, as far as we are aware, such a condition has not been observed.

[11] Loc cit., Taf. 23, fig. 24.

Cases in which the prerenal division of the postcava (pars hepatica and pars subcardinalis) is wanting, are undoubtedly due to the circumstance that, for some reason or other, the embryonic liver circulation has not been tapped by the right subcardinal vein (figs. 1 and 2). Blood from the liver therefore continues to reach the heart throughout all subsequent stages of development, as in fig. 1, through the V. hepatic communis (*V.H.C.*) which serves as the hepatic revehent vein in the adult. In variants of this character in which the postrenal division of the postcava is formed by the supracardinal veins, the renal veins open into the latter and also, on each side of the body, the sex vein opens into the renal vein. This is due to the persistence of the lateral portion of the renal collar on each side of the body, into which the renal and sex veins open, the latter through the postcardinals, and the retention of its connection only with the supracardinal vein. In such cases the lateral portion of the renal collar does not enter into the formation of the postcava and, as the pars subcardinalis of the postcava is wanting, the ventral portion of the renal collar (subcardino-postcardinal anastomosis, *Subc.Pc. Anast.*), has not been formed, or, at least, has not been carried into the adult stage.

The occurrence of variants of this character in the adult cat and man, serves as a complete confirmation of its presence in the embryo and of the morphological unity of the supracardinal system of veins.

16. *Persistence of the Cardinal Collateral Veins (The Marsupial Type of Postcava).*

With very few exceptions among marsupials, the postrenal division of the postcava lies ventral to the aorta and its iliac tributaries which is the reverse of the conditions usually observed in placental forms. This has been found by one of the writers[12] to be due to the circumstance that the postcava in the lumbar region is formed in marsupials by a fusion of two veins which takes place ventral to the aorta, and which have been termed the *Cardinal Collateral Veins.*

[12] McClure, C. F. W., *loc. cit.*, 1906.

Veins occupying a similar position to the cardinal collateral veins of marsupials are present in the embryo of the cat. They may form an extensive plexus of vessels which connect with the supracardinals dorsally, and encircle the aorta ventrally between the renal level and the origin from the aorta of the umbilical arteries. In the diagram (fig. 12) only the more caudally situated portion of the cardinal collateral system of veins (*CC*) is shown, where they form a venous ring with contiguous venous channels, on each side of the body, through which the umbilical artery passes. These rings are very constant in character in this location and the *ventral* or cardinal collateral portion of the ring has been found to persist both in the adult cat and man, as the *sole* pathway through which blood can reach the postcardinals or supracardinals, as the case may be, from the external (*E.Il.*) and internal iliac (*I.Il.*) veins. Cases in which the cardinal collateral veins have persisted in the adult are very rare and we know of only three instances, two in the cat and one in man, in which this condition has been observed. In the marsupials, on the other hand, it is the ventral or cardinal collateral (*C.C.*) element of this circum-umbilical venous ring which normally enters into the formation of the posteava in this region, while the dorsal element of the ring disappears.[13]

As far as we have observed, the cardinal collateral veins are very evanescent in character and do not play any especially significant rôle in the normal transformations of the embryonic veins in the cat. For this reason we have omitted them, for the most part, from our diagrams in order to avoid complications and too much detail.

17. *Persistence of the Renal Collar in the Adult.*

We know of three cases in man and none in the cat, in which a complete circum-aortic venous ring, the embryonic renal collar, has persisted in the adult. Now that we know the potential possibilities of the veins in this region, however, other cases of this type of variant will undoubtedly be found, not only in man, but also in the cat.

Instances in the adult in which the left renal vein passes dorsal to the aorta before joining the posteaval vein are also easily ex-

[13] McClure, C. F. W., *loc. cit.*, 1906, p. 203.

plained. This is brought about by the retention of a connection between the lateral portion of the renal collar on the left side and the supracardinal veins, and the atrophy of the anastomosis between the pars subcardinalis of the postcava and the left postcardinal vein (subcardino-postcardinal anastomosis).

The presence of multiple sex veins on one or both sides of the body, or of an anastomosis between the sex veins of opposite sides in the adult, has not proved a difficult matter to interpret, but may best be considered in detail at another time. Variants of this character are largely related, though not always, to atypical conditions of the embryonic subcardinal veins. No instance has yet been found, however, in which the continuous subcardinal channels in the lumbar region, as met with in the embryo (fig. 2), have been carried into the adult stage.

While for convenience of description we may classify the potential variant or atypical conditions of the adult postcava into 17 distinct types, we fully appreciate that combinations of these types may also occur. The circumstance, however, that we now possess a classification based upon a definite ontogenetic plan of the veins, seems to be a distinct advance over our former knowledge, as it not only permits us to interpret the atypical conditions of the postcava thus far observed, but also enables us to predict others which are potentially capable of occurring, and which still remain to be found.

Resumen por el autor, E. V. Cowdry,
Peking Union Medical College, Peking, China.

La Anatomía en China.

El presente trabajo es una breve relación de un estudio sistemático sobre las condiciones presentes y necesidades futuras de la ciencia de la Anatomía en China. Después de mencionar los factores principales en la introducción de la Medicina moderna en dicho pais, el autor publica una lista de todas las Escuelas médicas que funcionan actualmente en China, así como lo nombres de los anatómicos que enseñan en ellas, llamando la atención sobre la falta de anatómicos que puedan dedicar todo su tiempo a la enseñanza y la dificultad para obtener material para la disección.

También incluye en su trabajo la lista de socios, constitución y programa de la primera sesión de la Asociación Anatómica y Antropológica de China y discute la influencia de esta Asociación sobre el desarrollo de la Anatomía en el pais mencionado.

Translation by José F. Nonidez
Cornell Medical College, New York

First photograph of the Anatomical and Anthropological Association of China taken at the entrance to the Anatomical Laboratory of the Peking Union Medical College of the Rockefeller Foundation on February 27, 1920.

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED
BY THE BIBLIOGRAPHIC SERVICE, DECEMBER 6

ANATOMY IN CHINA

E. V. COWDRY

Anatomical Laboratory of the Peking Union Medical College of the Rockefeller Foundation

ONE FIGURE

INTRODUCTION

The following agencies are concerned in the development of modern medicine in China:

1. Foreign Missionaries: Most of the pioneer work has undoubtedly been accomplished through the energy and devotion of foreign missionaries who have labored faithfully in the face of prejudice and superstition. In 1913 the China Medical Missionary Association passed the following resolutions which make their purpose quite clear:

1). That in establishing medical colleges and hospitals our sole object is to bring the blessings of healing to the souls and bodies of the people of China, and to give a thorough training in medicine and surgery to young men and women of education and intelligence, enabling them as fully qualified doctors to be of the highest service to their country.

2.) That we have no desire to create permanently foreign institutions, and that our aim and hope is that these medical colleges will, gradually and ultimately, be staffed, financed, and controlled by the Chinese themselves.

3). That we desire to bring our teaching work into line with the regulations of the Ministry of Education, and in all ways to co-operate with and assist the Government of the Republic in medical education, so that a strong and thoroughly equipped medical profession may be established in this great land.

2. Foreign Agencies of Non-Missionary Character: The British Government has materially aided in the development of medicine in South China. It has been particularly successful in securing the support of wealthy Chinese in founding the Medical Depart-

ment of the University of Hongkong. Even the President of China showed his interest in the enterprise by establishing the "Ta Tsung T'ung Ch'uan Hsueh Fei" fellowship for university students. Unfortunately the war has depleted the Colonial Treasury, and, I have been told, the Chinese have shown less interest in the enterprise following the award of the German rights in Shantung to the Japanese. The school buildings, which are up-to-date in every particular, are situated on the side of the mountain and command a fine view of the harbor. The equipment is excellent, the surroundings the finest and most healthful along the South China coast, the facilities for preliminary education good; all that is needed to make the medical department one of the best and most attractive in China is an adequate full time staff. The Professor of Anatomy teaches also clinical surgery and the Professor of Physiology acts as Dean and teaches, in addition, microscopic anatomy. Members of the faculty are allowed to practise as consultants. To keep abreast of recent advances in medical education arrangements must be made for the maintenance of at least three full time men in each of the departments of Anatomy, Physiology and Pathology. The future of this institution is very bright in view of the broad minded attitude of the authorities, that it is the purpose of the Medical School to serve the whole of South China, not merely the Colony and Chinese of British nationality.

The Germans made good beginnings in Shanghai and Tsingtau which were interrupted by the war. The Shanghai School was located in the French Concession and was maintained in close affiliation with a strong engineering department which was financed largely by Krupp interests. After the seizure of the buildings, with part of the general equipment and library, by the French authorities, the teaching was transferred to the Tung Chi and Paulum Hospitals in the International Settlement. Most of the German instructors were deported and the remainder forbidden to enter either of these hospitals, so that at present most of the actual instruction is given to the students by two German doctors in private houses just across the street at Nos. 24 and 25 Burkill Road. There are 120 students and about 40 women

in the Nurses Training School. The institution is now called the Tung Chi Medical School and is apparently being maintained by the Chinese Government. Provision has been made for premedical and engineering work at Woosung and I have been told that the Peking Government has granted a sum of $300,000 for the construction of new buildings for these departments. Most of the information which I obtained at the office of the Commissioner of Foreign Affairs in Shanghai regarding Tung Chi proved to be unreliable and misleading. The other school, in Tsingtau, has been taken over by the Japanese authorities but is not being operated by them.

The Japanese Medical School in Mukden is unquestionably one of the best medical institutions in China. Its strength lies in its full time staff. It publishes a volume of researches each year which will bear careful study. While it is actually owned by the South Manchuria Railway it is nevertheless under strict governmental control. Hospitals are also maintained in nearly all of the large cities by an influential Japanese philanthropic society under the presidency of the distinguished statesman, Count Okuma. In view of the further consideration that a large number of Chinese physicians have received their training in Japan, it is not surprising that the Japanese exercise considerable influence in medical education.

Several American Universities have undertaken medical work in China. In the Yale-Hunan Medical School at Changsha a special attempt has been made to coöperate with the Chinese. This school has made headway in spite of its inaccessibility and the chronically unsettled condition of the province. The land and equipment of the Harvard Medical School in Shanghai was taken over in 1916 by the Rockefeller Foundation.

The China Medical Board of the Rockefeller Foundation is responsible for the most recent developments in medical education. Its purposes are clearly set forth in a letter, under date of March 15, 1915, from Mr. John D. Rockefeller, Jr., to the various missionary societies in Great Britain and the United States as follows:

1. To assist Missionary Societies to strengthen their medical schools and hospitals by providing equipment and other facilities, and by making annual grants, as may be found expedient, for the support of physicians and nurses, selected by the respective Missionary Boards, subject only to the Foundation's approval of the professional qualifications of the appointees.

2. With the consent of the Missionary Boards, to reorganize and expand existing medical schools, with their hospitals, and to support these, wholly or in part, from its own funds.

3. To aid other medical schools that are not strictly missionary.

4. To establish, equip and support new medical schools and hospitals. In choosing its agents, physicians and nurses for independent schools or hospitals, the Foundation will select only persons of sound sense and high character, who are sympathetic with the missionary spirit and motive, who are thoroughly qualified for their work professionally, and who will dedicate themselves to medical ministration in China. Beyond these qualifications, the Foundation cannot properly impose tests of a denominational or doctrinal nature, such as are deemed desirable by Missionary Boards for their own medical missionaries or agents.

The Board originally planned to establish two new medical schools, one in Peking and the other in Shanghai, but has recently decided to devote all its energies to the foundation and mainteance of one really first class school in Peking. To this end $7,000,000 have already been expended on buildings and equipment. The yearly budget is a large one owing to the fact that the entire staff is on a full time basis. It already amounts to about $750,000 per annum and will probably reach a million in the near future. The China Medical Board has also contributed generously toward the assistance of other medical schools and hospitals. Up to the end of 1918 payments totalling $676,889.70 were made to thirty-one institutions.[1]

3. The Chinese themselves.[2] The work of the Chinese Government should be given careful attention. The Army Medical

[1] Roger S. Greene, The Rockefeller Foundation in China, "Asia," November, 1919.

[2] "The Chinese government has discovered that it has a saving's account with a credit balance of five million dollars in the Russo-Asiatic Bank. The amount was placed there by the old Imperial Board of Education in Manchu days, when the department of education was one of the wealthiest in the government. Owing to the confusion incident to the change of regime, and the disappearance of the officials who deposited the money, the account was entirely lost sight of." (North China Star, May 13, 1920.)

School, the Naval Medical School, the National Medical College and the five Provincial Medical Schools constitute a creditable foundation on which to build. They represent a conscientious attempt on the part of the Chinese to assume responsibility for their own needs in the way of medical education. The late President, Yuan Shih-Kai, declared, that "For a country to be strong and prosperous it is essential that its citizens be healthy."

It is important that these medical schools should grow rapidly and become the back bone of the nation. Up to the present they have received very little foreign support and it is doubtful whether they will accept any. The Director of one of them told me that open coöperation with a foreign institution might have a bad effect upon his annual budget (owing to antiforeign feeling). Some medical missionaries, on the other hand, take but little interest in Chinese schools because they see in them no opportunity for evangelistic work. One doctor dismissed the question by saying that "it is difficult to coöperate with them because they are only heathens any way."

The case of the Kung Yee Medical College is instructive. This school belongs to a group of Chinese in Canton. It has excellent buildings in a fine location, and, until recently, had a fairly complete staff. The instruction given is of a relatively high grade. The educational policy of the institution was under the control of an executive committee in which foreign influence predominated. A proposal was made to become affiliated with the Canton Hospital (Missionary) which was apparently acceptable to all parties. At the last moment, unexpectedly and in an unconstitutional way, the Chinese members of the Kung Yee Society refused to ratify the agreement. The missionary element in Canton is almost unanimous in declaring that they can have no more confidence in the Kung Yee Society and that further negotiations are impossible. Affiliation has now been effected between the Canton Hospital and the Canton Christian College.

The Chinese schools have been unable to keep pace with the rapid advances in the foreign controlled institutions, which tend to attract the best students. With a depleted treasury the Chi-

nese may prove reluctant to make large expenditures to accomplish something which the foreigners will do for them gratis. Very skillful and diplomatic assistance is called for. As a rule the buildings and equipment are adequate for the present needs. It might be possible, however, to improve the library accommodations and to strengthen the teaching staff. The addition of one or two really well trained Chinese, who have travelled abroad, with a liberal salary guaranteed, to one of these colleges would soon react beneficially upon the whole institution. It is also desirable that members of the staff, already under appointment, should be given an opportunity to travel. Above all, research work should be encouraged. It might be a good idea to try the European policy of offering prizes and medals for the best work done. Perhaps the President of China would himself consent to make the awards.

The underlying difficulty, however, is the deeply rooted conviction, handed down for forty centuries, that the medical profession is but a fourth or fifth rate occupation. The sentiment of a nation like China cannot be changed over night nor yet in fifty years' time, but a beginning has been made in Peking, for example, where the splendid buildings of the Rockefeller Foundation will surely lead people to doubt whether, after all, the medical profession is so very degrading. The raising of a despised trade to the level of a dignified profession requires long and sustained effort throughout the country, but until it has been accomplished, we cannot hope for any real development of modern medicine in China.

The people generally look upon disease and sickness in an apathetic and fatalistic way, believing that it is a visitation of providence in punishment for their transgressions, or at any rate that it is the will of God, as our forefathers thought in Europe several hundred years ago and some continue to think. While such views prevail there can be no real progress. This tendency to shift the responsibility from their own shoulders is characteristic of the Chinese in all their dealings, and will be very difficult to correct. They are handicapped also by certain customs like foot binding, and the binding of the breasts in young women

before marriage, which they still practice blindly, having forgotten their origin and not troubling to ask the why or the wherefore.

Efforts to introduce modern medicine in China will be unavailing unless a nation-wide campaign is carried on by Chinese and foreigners alike for the education of public opinion. At present the graduates of the schools which have been established are regarded with indifference or active distrust by the vast majority of their countrymen. It is particularly difficult for those of them who have to go into the interior, away from the thin film of foreign influence, to live up to their new ideals, in the face of universal incredulity and without sympathy or assistance of any kind. A beginning is being made from several angles without proper coördination and on a very small scale. Professor John Dewey of Columbia University is perhaps doing more than any one man to divert the funds squandered by the millitarists into educational channels and to lead the mass of the people to see themselves as others see them and to assume full responsibility for the orderly development of their own lives. During vacations some of our students make a practise of giving public lectures on hygiene and preventive medicine; but what are one or two among so many? I am thoroughly in sympathy with Doctor Peter's public health campaign but I should like to see it on a much larger scale like the world-wide demonstrations of the International Health Board. The Chinese people are not devoid of business instinct and I am inclined to think if it were demonstrated to them repeatedly how much may be actually gained by improved sanitation and through an intelligent appreciation of the principles of hygiene, that they would not be unresponsive. Every means of publicity should be utilized and the vernacular press pushed to the limit in a concerted attempt to educate the general masses of the population to a realization and appreciation of the good work which is being done in the medical schools and hospitals throughout China, emphasis being placed upon those under Chinese control.

At the same time wealthy merchants and business men should face their duty to their country. It would not be at all a difficult matter to select a group of five or six Chinese in each of the great

cities of Kankow, Shanghai and Canton who could, with but little personal sacrifice, establish and maintain a medical school on an equally efficient and elaborate scale to that founded through the generosity of an American citizen in Peking. The example has been set and I think that we can count on its being followed.[3]

A list of the medical schools with the names of the anatomists follows. Those marked with * were personally visited.

Canton

1. *Kwangtung Provincial Medical College.
2. *Hackett Medical College for Women.
   Harriett M. Allyn (part time)
   S. W. Kwan (part time)
3. *Kung Yee Medical School
   D. J. Todd (part time)
   J. A. Hofmann (part time)
   John Kirk (part time)

Tientsin

25. *Naval Medical School

Tsinanfu

26. *Shantung Christian University (1918–19)
    R. T. Shields
    L. M. Ingle
    Wu Djao Hsiang
    Wang Hwei Wen

BUILDINGS AND EQUIPMENT

The anatomical laboratories in China vary from a single bare room to costly buildings fitted with every convenience. The anatomical laboratory of the Peking Union Medical College, here illustrated is certainly the most elaborate. The anatomical laboratories of the Japanese Medical School in Mukden are housed in a plain but substantial building and are fully equipped with everything necessary for teaching and research. The University of Hongkong has good reason to be proud of the School of Anatomy erected in a splendid location, high up on the mountain side largely through the generosity of the late Mr. Ng Li Hing, one of the leading merchants of the colony. Mention should also be made of the new anatomical laboratory of L'Aurore University, the austere simplicity of which is quite pleasing. Some of the Chinese institutions are a strange mixture of the old and the new. Occasionally one may see mirrors placed at the top of a flight of

stairs, and in other strategic positions, in order to turn back the evil spirits and in this way make the place more healthy.

I shall not take space to describe the smaller laboratories, some of which are very unprepossessing, except to say that good work may be done with very meagre equipment if it is gone about in the right way. One becomes very tolerant in China. From modest beginnings great developments may be expected. The mere rudiments of anatomy properly or even indifferently taught will serve to indicate the fallacy and the danger of native Chinese medicine. Our policy is to encourage and stimulate, not to go away with the feeling that the conditions are hopeless.

Both large and small institutious suffer from lack of library facilities. At present there is no library in the whole of China to which one can refer for back numbers of standard European journals. Some are to be found in Peking (where the library of the Peking Union Medical College is being rapidly enlarged) one or two in Shanghai and a few more in Hongkong. Tung Chi has a few valuable sets of German journals. Under these conditions teaching is hampered and research work is set aside because it is not altogether satisfactory to have to devote time and energy to a problem which may already have been solved by some one else. Dr. Greenman's policy of the wide distribution of the Wistar journals in China is most helpful and constitutes an important step in the right direction. The relatives of the late Mr. Andrew Carnegie could make no more fitting memorial to him than the establishment of a real library in China, free to millions of people.

STAFF

The twenty-six medical schools of China number only about two dozen teachers who are able to devote all their time to anatomy. These teachers are certainly overworked but their plight is not so bad as those who have to teach a whole variety of subjects and sometimes have to attend to hospital and, more rarely, to private practice in addition. Often the instructors are so busy that they have neither the time nor the energy to settle down and do one thing well, with the result that makeshifts and time saving devices are resorted to. Chinese medical schools are

inferior to those of Japan in this respect. It is not that those in authority fail to appreciate the gravity of the situation; they are simply unable to remedy it through lack of funds. In several schools, however, one cannot help feeling that some of the money invested in buildings could more profitably have been spent on the staff. The teachers suffer with the students. They leave promising, perhaps remunerative, careers behind them and come out to China young and enthusiastic. They have innumerable demands upon their time and energy, they do really pioneer work in isolated stations, and become, to some extent, 'Jacks of all trade.' Middle age finds them often with large families, but without that modern prerequisite—a specialty—so that they are just a little out of the running for positions in the modern and up-to-date medical schools which are bound to spring up. It is essential that anatomists and others shall have a certain amount of leisure time to plan their teaching, to keep up with world progress and to engage in research. Unfortunately it is always easier to secure funds for buildings and equipment, which represent something tangible and permanent, than for the salaries of teachers and investigators. With patience, however, the condition in China will slowly improve.

TEACHING

With foreigners of so many nationalities it is not surprising that the methods of teaching anatomy should be varied. Perhaps the most pernicious system is as follows: The foreign instructor, who speaks not a word of Chinese, comes in and makes anatomical drawings on the blackboard and labels the parts. A Chinese interpreter then makes his appearance and translates the terms into Chinese. When the students return next day they are required to repeat the drawings from memory. They have no practice in dissecting, even on animals, and accordingly have to learn how to use their instruments upon the living subject, sometimes with disastrous results. One of my questionnaires was answered as follows:

"We don't teach histology, embryology, comparative anatomy, as our scope is to form practitioners only. Besides, the intel-

lectual standard and scientific previous education of our scholars are not high enough to allow us to emphasize pure science."

The greatest stumbling block in the teaching of anatomy, next to inadequacy of staff, is the difficulty of obtaining human material for dissection. To the best of my knowledge only the Japanese Medical School at Mukden and the University of Hongkong have a sufficient and regular supply of bodies on which they can rely. Only twelve of the twenty-six medical schools offer regular courses in human dissection. In Peking we have only been able to secure four bodies in the last year and a half. When the first entered the building all our servants left us immediately and we had some difficulty in replacing them. The police and the authorities generally are not sympathetic, and there seems to be but little hope of obtaining sufficient material in Peking for sometime to come. In the provinces some of the schools obtain material from executions but this source is sporadic and unsatisfactory. It is interesting that in Japan, where the worship of ancestors is also prevalent, bodies may be obtained more easily than perhaps anywhere else in the world (Cowdry '20, p. 72).

The regulations regarding dissection of the Chinese Government are as follows, quoting the translation given in the China Medical Journal:

Order of the Board of Interior No. 51, November 22, 1913:

Article I. A physician, in case of death from disease, may dissect the body and inspect the diseased part to determine (examine) the origin of the disease, but he must first obtain the consent of the relatives of the dead person and clearly inform the local magistrate before proceeding to dissection.

Article II. The police and inspectors, in case of mysterious death, the cause and origin of which cannot be accurately ascertained without dissection, may appoint a physician to dissect said corpse.

Article III. The bodies of all those meeting death by punishment or dying in prison from disease, without relatives and friends to claim their bodies, may be given by the local magistrate to a physician for dissection, to be used for the purpose of experimentation in medical science, but after dissection the body must be sewed up and buried.

Article IV. If any are willing for the benefit of science to offer their bodies for dissection and leave word to that effect before death, they may do so, but the whole body must be sewed up and returned to his or her family after dissection.

Article V. These regulations are in force from the day of their proclamation.

Supplementary order of the Board of Interior, No. 85, April 22. 1914.

Article 1. All medical colleges and hospitals, which are proved to be in good condition by the local authorities and recognized beforehand by the Board of Education or established by the public, shall be allowed to perform dissections.

Article 2. According to Acts No. 1 and 4 of the General Laws this may be enforced and the medical men allowed to perform post-mortems as soon as the consent of the family is obtained. (During summer this may be done immediately after reporting to the local authorities.)

Article 3. When the colleges and hospitals mentioned in Art. 1 of By-laws apply for any dead body from the local authorities the following rules must be observed:—

i. Proper letters with official seals are needed on both sides—local authorities and the college when dealing with any deceased criminal or deceased prisoner. Any private medical college recognized by the Board of Education may also apply in similar manner.

ii. Special certificates shall be made by the judicial authorities of the local government, and the same shall be given at the time when dead bodies are issued to the medical colleges. After examination the certificates shall be kept in the college until the end of the month when they shall be returned to the local authorities so as to enable them to preserve records. There shall be no need to send these to the prisons.

iii. The name, age, district, and number of the dead person shall be noted in the certificate, which shall be properly dated with official seals by the local government before the same is sent. The college receiving the corpse shall keep a copy of the name, age, date, etc., so as to facilitate examination when required.

Article 4. A certificate of death by a qualified medical man shall first be sent to the local authorities before a post-mortem examination is allowed on certain persons, who have not died in a hospital as mentioned in Art. 4 of General Laws. After examination a report shall be submitted to the local authorities for reference.

Article 5. With the exception of Arts. 1 and 4 of General Laws any or many parts of a dead body dissected may be retained, if such are necessary for medical demonstration. This may be done according to Art. 3 of General Laws.

Article 6. When any or many parts have been removed from a dead body for medical demonstrations, the rest of the corpse shall, if possible, be sewed up according to Arts. 3 and 4 of General Laws. (Dead bodies mentioned in Art. 3 of General Laws which are supplied to medical colleges shall be treated in the same way.)

Article 7. A dissected body after being sewed up shall be returned to the family if possible. If unclaimed it shall be buried by the college which has dissected the body. After the funeral, a sign shall be shown

on the tomb where the deceased has been buried. (Any deceased person having no family as mentioned in Art. 3 of General Laws may be taken to a crematorium by the medical college and cremated if necessary. After burning, the ashes of the deceased shall be gathered and buried, and proper signs shown on the tomb. This shall be duly reported to the local authorities.)

Article 8. All medical colleges shall report yearly the number of dead bodies dissected, to the police court if at Peking, and to the local authorities at other places, in order to facilitate reporting to the Board of Interior for the preservation of the records.

Article 9. These By-laws may be revised at any time with a view to improvement.

Article 10. These By-laws shall be enforced on date of promulgation.

The chief difficulty is that these regulations are interpreted to mean that the written consent of the individual before death must be supplemented by the sanction of the relative, which it is almost impossible to obtain.

Owing to the pressure of other duties, the teachers are often unable to properly adapt their methods of teaching to the lack of human material. They soon come to rely upon the use of anatomical models made in Europe or Japan and give up their efforts to obtain bodies for dissection; for it takes a lot of time and energy to cultivate the authorities, to drink endless cups of tea, to make petitions for favorable legislation and arrangements for executions. Yet it is possible, with a little care, to give the students an idea of the science of anatomy without the aid of human dissection. It is usually quite a simple matter to obtain a skeleton from abroad or even in China. For instance, the students at Paotingfu have, through their own initiative, amassed quite an interesting and useful collection of bones from the graves in the vicinity. Living models should be used extensively. The students should be obliged to make a careful and complete dissection of some mammal comparing the structure carefully with that of man. In the south of China advantage may be taken of the monkeys which are sold as pets, for from two to five dollars a piece.

Lack of time and insufficient laboratory equipment are responsible, in some cases, for a rather low standard of work in histology, embryology and neurology.

While the teaching in the better schools is worthy of the highest praise, there is a general tendency, which I have already noted in the case of the Japanese medical schools, to give too many lectures and too little laboratory work. It is true that the cost of laboratory furnishings may be a certain deterrent; but, on the other hand there is the time factor. It is more wearing on the teacher to give one hundred lectures than to teach in the laboratory for the same length of time. The proportion of lectures to laboratory work in some of the principal colleges is given in table 1.

TABLE 1

Proportion of lectures to laboratory work in anatomy[4]

COLLEGE	LECTURES	LABORATORY
	per cent	*per cent*
Army Medical School	83.0	17.0
Chekiang Provincial Medical College	86.6	13.4
Chihli Provincial Medical College	91.3	8.7
École de Medicine Franco-Chinoise	100.0	0
Hackett Medical College	35.8	54.2
Hangchow Hospital and Medical Training College	80.0	20.0
Hunan Yale Medical College	32.7	67.3
Japanese Medical School, Mukden	50.0	50.0
Kiangsu Provincial Medical College	71.4	28.6
Kung Yee Medical College	36.9	63.1
Liang-Yueh Medical College	80.0	20.0
Peking Governmental Medical College	70.4	29.6
Peking Union Medical College	10.0	90.0
West China Union University	40.5	59.5

This high percentage of lectures is very bad for the students. It means that most of their information comes to them second hand, predigested in the mind of the lecturer, and that they are, to a large extent, robbed of the incentive and privilege of making observations for themselves and of learning how to make logical deductions therefrom. This method of training does not teach the student self reliance, which is particularly necessary in China, where, after graduation, he is often placed entirely on his own resources without sympathetic and stimulating help from those around him.

[4] Unfortunately information has not yet been received from St. John's University.

In some colleges the time devoted to anatomy is altogether too long. I learn for example, from the Kung Yee Medical College, in answer to my questionnaire, that the students suffer 1178 hours of instruction in anatomy. Long hours with lack of time to think and of opportunity to pursue work along special lines, chosen by the students themselves, is deadening. It usually fails to create in the student a thirst for knowledge and a desire to help himself.

There is one more consideration in the training of the student which should, in my opinion, receive attention in view of the fact that it is the purpose of the medical schools to turn out men of strong character, not merely physicians skilled in their professions. Reading through the printed announcements of the various colleges we meet with catagorical prohibitions relating to the conduct of the students. A merely negative attitude of this kind does not itself tend to strengthen character. When all restraint is removed and the student leaves the college a reaction is in danger of setting in. It is surely through education, teaching that what is right is also expedient, that the best results are to be obtained.

The standard of instruction has unquestionably been raised by the action of the Council on Medical Education (1915) in urging the various medical schools to meet the following requirements necessary for admission to "Grade A:"

1. Course of Instruction. That the course of instruction shall extend over a period of five years of, at least, 32 weeks each.

That the text books used and the instruction given shall be equivalent to that in European and American schools.

That human dissection, and complete courses in laboratory work, shall be included in the curriculum.

2. Entrance Requirements. That the standard of admission shall be graduation from a Middle School as defined by the Educational Association of China, and, in addition, at least one year of preliminary work including laboratory courses in physics, chemistry and biology; this preliminary or "pre-medical" year being arranged to supplement the preparatory instruction already given in Middle Schools.

3. Hospital Year. That before receiving a medical degree, students who have completed the five years of regular instruction, shall spend one year as interne in an approved hospital, or in some other line of special medical work, at the conclusion of which the applicant for a degree shall present a thesis acceptable to the faculty of the medical school.

4. Degrees. That only students who have met the entrance requirements, have completed the regular course of instruction in an approved school, and at the termination of the hospital year have presented an acceptable thesis shall be entitled to receive a medical degree.

5. Staff. That the minimum staff shall be ten men on the field giving full teaching time. To provide for furloughs, language study, etc., this requirement means a staff of at least fifteen fully qualified teachers either foreign or Chinese.

6. Equipment. The school must be adequately equipped with modern appliances for instruction, properly equipped laboratories in Chemistry, Pathology, Bacteriology, Anatomy, and Clinical Microscopy, and must be maintained on an efficient basis. The scientific instruments and apparatus shall be sufficient to permit students to do individual work.

7. Hospital Facilities In connection with each medical school and under control of the faculty, there shall be one or more hospitals suitable for teaching purposes, each hospital to have at least 100 beds. One or more daily dispensaries should be connected with the college hospital.

8. Curriculum. The schools approved by the C. M. M. A. shall meet the curriculum requirements which the Council on Medical Education will prepare in detail upon the lines already suggested.

While travelling from college to college one is impressed with the relatively small attendance. Very few of the colleges are filled to capacity. This is to be attributed to the fact that the science of medicine does not appear to be very attractive to Chinese students, rather than to the lack of premedical training which may easily be secured in Peking, Shanghai, Hongkong and the larger cities. It is difficult to ascertain the maximum number

of students which may enter the medical schools of China each year, because in the poorer schools, where but little attention is given to laboratory work, almost any number may attend the lectures. The Chinese Government Schools are certainly much better attended than the missionary establishments, perhaps because their entrance requirements are less exacting. Table 2 will show how meagre is the supply of doctors which is being trained to supply the needs of 400 million people. The entering classes of 16 colleges combined only contain 355 students. Contrast this with the conditions following the war in the United States and Canada. The University of Toronto, for instance, has an entering class in the medical school of 416 students to supply the needs of a country with a population of about 8 millions, already quite well stocked with doctors.

During the last few years the following medical schools have been closed, partly through a desire to concentrate activities and thus increase the standard of work:

Harvard Medical School, Shanghai.
Women's Medical School, Soochow.
University of Nanking Medical School, Nanking.
Union Medical College, Hankow.
German Medical School, Tsingtau.
Provincial Medical School, Wuchang (?).

The following resolution of the Council on Medical Education (1920) seems to forecast the closure of other schools through lack of adequate support:

> That in view of the difficulties hitherto experienced in securing adequate staff and support for the medical schools at Changsha, Chengtu, Mukden and Foochow, the Association would commend to the incoming Council the careful consideration of the following question, in consultation with the missions interested in the development of those schools:
>
> *a*. Whether steps can be taken to meet the urgent need of a broadened basis of support for the Medical School at Changsha, by the provision of an adequate endowment, or by the full co-operation of missions working in that area, in view of the fact that should this not be obtained, the continued existence of the school will prove impracticable.
>
> *b*. Whether the Missions at work in Southwest China can set aside a sufficiently large staff of efficient teachers to enable the West China

Union University Medical Department to approximate to the C. M. M. A. minimum requirements.

c. Whether some measure of co-operation between the Union Medical College, Mukden, and the School of Medicine, Tsinan, could not be satisfactorily arranged.

d. Seeing that the Fukien Christian University is not intending to develop a medical department, as the Council is informed, should not the authorities of the Fukien Medical College be urged to reconsider the continuance of that school?

TABLE 2

Actual attendance and teaching capacity

COLLEGE	ACTUAL NUMBER IN FIRST YEAR	MAXIMUM NUMBER
Army Medical School	51	85
Chihli Provincial Medical College	42	45
École de Medicine Franco-Chinoise de Canton	25	
Hackett Medical College	14	
Hangchow Hospital and Medical Training College	21	50
Hangchow Provincial Medical School	30	80
Hunan Yale College of Medicine	7	
Japanese Medical School, Mukden	57	60
Kung Yee Medical College	20	40
Kwangtung Provincial Medical College	25	50
Kwang-Wha Medical College	14	25
Liang-Yueh Medical College	8	
Peking Union Medical College	7	25
Shantung Christian University ('19–20)	10	30
Soochow Provincial Medical School	14	60
West China Union Univesrity	10	

Women of the better class are gradually becoming interested in medical education and the outlook for the future is good. At least six medical schools welcome them in China, whereas in Japan they are permitted to enter only one, and that of distinctly inferior grade. Notwithstanding the fact that a beginning has been made in coeducation, and the initial prejudices of a very conservative race partly overcome, there is a strong movement for the strengthening and maintenance of at least two medical schools exclusively for women, one in the North or Central China and the other in the South, which shall be in large measure staffed and controlled by women. The wisdom of introducing

a system of education into China which has not proved eminently satisfactory in Europe or America is doubtful. It is fair, I think, to say that in the United States the best students seek to enter Hopkins, Chicago and other coeducational institutions in preference to the women's medical colleges, in which it has never been possible to establish an equally high grade of instruction. If China is to keep abreast of the times, it is essential that her women shall be encouraged to come out and exercise their influence, not to retire into the seclusion of feminine institutions.

RESEARCH

It is not an easy matter to carry on research work in China. One of the greatest obstacles is geographical isolation enhanced by insufficient library facilities. The country is so vast and the number of anatomists so small that each must rely almost entirely upon his own resources. In order to bring together men and women of like interest and to create a stimulating intellectual atmosphere an "Anatomical and Anthropological Association of China" was formed at a meeting held on Thursday afternoon, February 26th, 1920, in the anatomical laboratory of the Peking Union Medical College, as follows:

HONORARY MEMBERS

Aleš Hrdlička, *U. S. National Museum*, Washington, D. C.

ACTIVE MEMBERS

Andersson, J. G., Peking, (*Councillor*)
Black, Davidson, *Department of Anatomy, Peking Union Medical College*, (*Councillor*)
Boring, Alice M., *Department of Biology, Peking Union Medical College.*
Britland, A. J. D., *Peking Union Medical College Hospital.*
Brubacker, A. F., Lia Chow, Shansi.
Chang, P. C., *Department of Anatomy, Chihli Provincial Medical School*, Paotingfu.
Chen, S. P., Tsung Pu Hutung, Peking. (*Councillor*)
Cowdry, E. V., *Department of Anatomy, Peking Union Medical College*, (*President*)
Cowdry, N. H., *Department of Anatomy, Peking Union Medical College.*

CHUAN, S. H., *Director, Army Medical College, Peking,* (*Councillor*).
DANTON, G. H., *Tsing Hua College,* Peking.
DIGBY, KENELM, H., *Department of Anatomy, University of Hongkong,* Hongkong.
DITTMER, E. G., *Tsing Hua College,* Peking.
DOBSON, R. J., *Peking Union University,* Peking.
EARLE, H. T., Dean of the Medical Faculty, *Victoria University,* Hongkong, (*Councillor*).
FAUST, F. C., *Department of Pathology, Peking Union Medical College.*
GRAY, DOUGLAS, *Physician to the British Legation,* Peking.
HARDING, B. M., I Chow Fu.
HODGES, P. C., *Peking Union Medical College Hospital.*
HOWARD, H. J., *Department of Ophthalmology, Peking Union Medical College.*
HSIEH, E. T., *Department of Anatomy, Peking Union Medical College,* (*Councillor*).
INGLE, L. M., *Department of Anatomy, Shantung Christian University,* Tsinanfu, Shantung.
INGRAM, J. H., *American Board Mission,* Peking.
INOUYE, M., *Department of Anatomy, Tokyo Imperial University,* Tokyo, Japan.
LI DING, *Department of Anatomy, Hangchow Provincial Medical School,* Hangchow.
LI PAU CHEN, *Department of Anatomy, North China Union Medical School for Women,* Peking.
LIEU, T. C., *Hunan-Yale Medical School,* Changsha, Hunan.
MAIN, D. DUNCAN, Hangchow.
MAXWELL, J. P., *Peking Union Medical College.*
MEDHURST, C. SPURGEON, Peking.
MORSE, W. R., Changtu, West China.
MERRINS, E. M., *St. John's University,* Shanghai, (*Councillor*).
NEAL, J. B., *Shantung Christian University,* Tsinan, Shantung.
ONO, SHUNICHI KOISHIKAWA, Kobinatadai II, No. 35, Tokyo.
PACKARD, CHARLES, *Department of Biology, Peking Union Medical College,* (*Secretary-Treasurer*).
PHILLIPS, E. MARGARET, 13 Nan Wan Tzu Hutung, Peking.
PORTER, L. C., *Peking University,* Peking.
PORTERFIELD, W. W., *St. Johns University,* Shanghai.
RIDGE, W. S., Peking.
READ, BERNARD E., *Department of Physiological Chemistry, Peking Union Medical College.*
ROSENIUS, ELSA, Peking.
SCHUMAKER, ARTHUR, Tsung Pu Hutung, Peking.
SHIELDS, R. T., *Department of Histology and Embryology, Shantung Christian University,* Tsinanfu, Shantung, (*Councillor*).
SNELL, HOHN A., Soochow.
STEVENSON, P. H., Lu Chow Fu, Anhui.
STONE, R. S., *Department of Anatomy, Peking Union Medical College.*

TANG, E. H., *Director, National Medical College*, Peking. (*Councillor*).
TAYLOR, H. B., Anking.
TING, V. K., *Director, Geological Survey*, Peking, (*Councillor*).
VAN BUSKIRK, J. D., *Severance Union Medical College*, Seoul, Korea.
WILDER, J. W. D., Peking.
WILLIAMS, J. D., *Department of Anatomy, Hunan-Yale Medical School*, Changsha.
WU LIEN TEH, Peking.

CONSTITUTION

1. The Association shall be called the Anatomical and Anthropological Association of China.

2. The object of the Association shall be to advance the sciences of Anatomy and Anthropology in the Far East, in the broadest sense, especially in the coördination and centralization of activities, in the improvement of conditions for teaching and research and in the financing of special investigations and expeditions.

3. All persons who are interested in the objects of the Association shall be eligible for membership.

4. The names of candidates for membership shall be submitted to the Secretary-Treasurer at least one month before the meeting at which they come up for election.

5. Each member shall pay an initiation fee of $2.00 to the Secretary-Treasurer.

6. Annual dues shall be determined at the first annual meeting.

7. Members duly elected shall be able to assume life membership by the payment of $50.00, it being understood that the Association does not assume any obligations with respect to publications.

8. Upon the recommendation of the Council persons who further the interests of the Association either financially or in other ways shall be elected patrons of the Association.

9. The officers of the Association shall consist of a President, elected annually; and a Secretary-Treasurer, and twelve councillors, elected to serve for a period of two years.

10. The Council shall meet at the call of the President, in the interval between annual meetings for the consideration of expenditures, of recommendations for membership, and for the arrangement of programmes for meetings. The Council shall also deal with all other matters of concern to the Association and make recommendations to it for decision.

11. Annual meetings of the Association shall be held in close affiliation with the China Medical Missionary Association.

12. Special Meetings shall be held at the discretion of the President and at least three members of the council.

13. For the election of members, changes in constitution, extraordinary expenditures, and dropping of members, a three-fourths vote of those present will be required; for all matters of minor import, a simple majority vote will be sufficient.

PAPERS PRESENTED AT THE MEETING

1. *Relations of Anthropology to Medicine.* Aleš Hrdlička, U. S. National Museum, Washington, D. C.
2. *The Attitude of the Chinese Government towards Dissection.* S. P. Chen, Official Representative of the Board of Interior.
3. *The Jewish Colony at Keifengfu.* Dr. C. D. Tenney, American Legation, Peking.
4. *Stone Implements of Neolithic Type in China.* J. G. Andersson, Peking.
5. *Head Flattening.* E. T. C. Werner, Peking.
6. *Anthropologisches Studium Ueber Unterextremitaten der Chinesen.* Kotaro Shiino, Department of Anatomy, South Manchuria Railway Medical School, Mukden. (Read by title.)
7. *Observations made at the Second Chinese Government Animal Experimental Station.* Chou Wei-lien, Director.
8. *Methods of Anthropometry.* Aleš Hrdlička, U. S. National Museum, Washington, D. C.
9. *Ueber die Panethschen Zellen des Duodenums von Schweinen.* E. H. Tang, Director, Government Medical School, Peking.
10. *A Review of Chinese Anatomy from the Period of Huangti (Yellow Emperor 2697 B. C.).* E. T. Hsieh, Department of Anatomy, Peking Union Medical College.
11. *Seal Characters with Special Reference to Anatomical Terms.* J. H. Ingram, Peking.
12. *The Skull Measurements of Three Hundred Chinese.* S. H. Chuan, Director, Army Medical College, Peking.
13. *Height, Weight and Chest Measurements of 860 Chinese Students.* S. H. Chuan, Director, Army Medical College, Peking.
14. *Height, Weight and Chest Measurements of Healthy Chinese.* A. C. Hutcheson, Nanking.
15. *A Comparative Study of Physical Measurements of Chinese Students.* Arthur Schumaker, Peking. (Read by title.)
16. *The Origin of the Vitreous.* Harvey J. Howard, Peking Union Medical College, Peking.
17. *The Secretion of Urine in the Camel.* B. E. Read, Peking Union Medical College, Peking.
18. *The Application of X-Ray Study to Certain Anatomical Problems.* Paul C. Hodges, Peking Union Medical College. (Read by title.)
19. *A Report on the Wistar Institute of Anatomy and Biology and its Relation to Biology in China.* Chi Ping, The Wistar Institute, Philadelphia, Pa., U. S. A. (Read by title.)
20. *The Comparative Anatomy of the Mastoid Region.* Jui Hua Liu, Peking Union Medical College.
21. *The Endocranial Anatomy of Oreodon (preliminary report),* Davidson Black, Department of Anatomy, Peking Union Medical College.
22. *The Birds of North China.* G. W. D. Wilder, Peking.

23. *The Innervation of the Soft Palate.* M. Inouye, Department of Anatomy, Tokyo Imperial University, Tokyo, Japan.
24. *The Relation of the Interstitial Cells of the Reproductive Organs to Secondary Sex Characters in the Domestic Chicken.* Alice M. Boring, Peking Union Medical College.
25. *A Study of the Differentiation of Blood Cells in the Bone Marrow with the Aid of Janus Green and Other Supravital Dyes.* E. V. Cowdry, Department of Anatomy, Peking Union Medical College. (Read by title.)
26. *Some Growth Chances in the Walls of the Thorax in the Fetus.* C. K. Roys, Department of Anatomy, Shantung Christian University, Tsinanfu. (Read by title.)
27. *The Surgical Anatomy of the Ovary with Special Reference to the Blood Supply.* S. J. Kirkby-Gomes, Peking. (Read by title.)
28. *Cytological Reinvestigations on the Somatic Cells of Ascaris with Special Reference to Mitochondria.* ScunIchi Ono, Tokyo.
29. *The Effect of Starvation and Refeeding upon the Mitochondria, the Golgi Apparatus, and other Cytoplasmic Constituents.* ShunIchi Ono, Tokyo.
30. *The Effect of Radium on Cell Division.* Charles Packard, Peking Union Medical College.
31. *The Present State of the Schistosome Problem.* E. C. Faust, Peking Union Medical College.
32. *Problems under Investigation in Connection with the Collection of Human Embryos.* E. V. Cowdry, Department of Anatomy, Peking Union Medical College. (Read by title.)

DEMONSTRATIONS

1. *The Innervation of the Muscles of the Soft Palate.* Michio Inouye, Department of Anatomy, Tokyo Imperial University.
2. *Preparations of Mitochondria in the Somatic Cells of Ascaris.* ShunIchi Ono, Tokyo.
3. *Preparations Illustrating the Effect of Starvation and Refeeding upon the Mitochondria, the Golgi Apparatus and Other Cytoplasmic Constituents.* ShunIchi Ono.
4. *Experimental Alterations on the Mitochondria of Plant Cells.* N. H. Cowdry, Department of Anatomy, Peking Union Medical College.
5. *Microscopial Preparations of the Interstitial Cells of Sebright Testes.* Alice M. Boring, Peking Union Medical College.
6. *A Demonstration of the Behavior of Mitochondria in Bone Marrow Cells by Supravital Staining with Janus Green.* E. V. Cowdry, Department of Anatomy, Peking Union Medical College.
7. *Schistosome Larvae in Man and Other Animals.* E. C. Faust, Peking Union Medical College.
8. *Methods of Anthropometry.* Aleš Hrdlička, U. S. National Museum, Washington, D. C.

9. *A Demonstration of Some of Professor Dogiel's Original Preparations of Nerve Endings.* Shunlchi Ono, Tokyo.
10. *Preparations Illustrating the Effect of Feeding Meat and Fat upon the Mitochondria in the Acinus Cells of the Pancreas of the Guinea Pig.* Ma Wen Chao, Department of Anatomy, Peking Union Medical College.

It is hoped that this Association will open up lines of investigation which were formerly closed to anatomists as individuals, and that it will be successful in enlisting the active coöperation of many workers who are not professional anatomists.

China is a veritable *terra incognita* which offers unique opportunities for pioneer work along certain lines. The establishment of the U. S. National Research Council, alone, is sure indication that science is passing from an individualistic to a coöperative basis. As Dr. Livingston aptly remarks: "It has been occasionally suggested that one of the reasons for the slow advance of science lies in the fact that scientific research problems are still generally attacked by individuals or by small, local groups of workers influenced by a single individual, rather than by planned coöperation among a number of workers in different institutions. Individualistic research has been characterized, by the late Professor C. E. Bessey, as a kind of guerilla warfare upon the unknown." The wonderful discoveries which were made during the war are due to the fact that in a national emergency individual plans and aspirations are abandoned and coördination becomes the order of the day.

In the Orient, racial problems are uppermost, several of which have been indicated in a recent address by Hrdlička (1920). Anatomists are certainly in a position to contribute valuable information relating to the physical standards and potentialities of the Chinese race, which, in the last analysis, must form the basis for the adjustment which is bound to take place between the East and the West. If an arrangement can be made whereby careful records are kept of all the dissections carried on in the principal medical schools for a period of five or six years, a number of interesting facts are sure to be brought to light. A tabulation of the frequency of the chief progressive and regressive variations will be helpful in forming an opinion as to whether the

Chinese are a progressive or regressive type, and will, perhaps, indicate what evolutionary tendencies they exhibit along certain lines. Realizing that a thorough knowledge of physical standards is also prerequisite to any concentrated programme for public health work in China the members of the China Medical Missionary Association, through their Research Committee, have made a special study of the height, weight and chest measurements of healthy Chinese, and further investigations along similar lines are contemplated.

Friendly coöperation is also necessary for the successful study of vertebrate palaeontology and in order to collect data bearing upon the ancestry of man. We are told (Matthew, 1915) that mankind differentiated in Central Asia and migrated from this region to all parts of the world, and there seems to be a strong probability that in the course of time "missing links" of great importance will be discovered in China. The Director of the Geological Survey of China appreciates the importance of this type of investigation and has indicated his willingness to coöperate, so that a well organized attempt is now being made to collect specimens and data. A movement has also been set on foot in Peking largely through the initiative of Dr. Hrdlička, for the establishment of a Natural History Museum. At present research work along several lines is greatly handicapped through lack of museum facilities. A few isolated collections occur here and there, made chiefly by private individuals. Those of Arthur Stanley and of Kurz in Shanghai, and of Gee in Soochow, are of special interest. Through the generosity of the Rockefeller Foundation our own laboratory is well equipped for comparative work.

An attempt is being made to stimulate research work in embryology through the collection of Chinese embryos and fetuses, and by offering facilities for their study. In less than a year 83 specimens have been collected and we have managed to arrange for the shipment of specimens from different parts of the country to Peking. While most of them come at present from hospitals under foreign control we are unremitting in our efforts, with the help of our students and graduates, to obtain them directly

from native physicians because this source, if it can be made available, should prove to be almost inexhaustible.

Thus far I have referred to the desirability of coöperation in the collection of specimens and data; the more difficult type of coöperation, in actual laboratory experimentation directed toward the solution of definite anatomical and biological problems, though very desirable, will probably not be realized in China for many years to come on account of the dearth of persons trained in experimental work.

Report on Medicine in China by the China Medical Commission of the Rockefeller Foundation, 1914, University of Chicago Press.

Resumen por el autor, Eugene L. Settles,
University of Missouri.

Los efectos de una dieta grasa abundante sobre el crecimiento del tejido linfoide.

Dos gatos jóvenes procedentes de la misma cría fueron alimentados durante cuatro meses y medio, uno con leche que contenía 6 por ciento de grasa, el otro con la misma cantidad de leche con 3 y medio por ciento de grasa, suplementada en el caso del primero por carne grasa y en el último por carne magra. Despues del primer mes ambos presentaban excelente salud. El gato que recibía alimento rico en grasa presentaba un exceso en el peso del cuerpo y órganos, como indican las siguientes cifras: Peso total (despues de deducir el exceso de grasa), 30%; timo, 84.8%; glandula linfática mesentérica, 52.7%; bazo, 23.8%; hígado, 93.7%; páncreas, 80.6%; tibia izquierda, 44.1%; fémur izquierdo, 34.6%; corazón, 21.1% y riñones, 27 por ciento.

De estas cifras se deduce que el timo y la glándula linfática mesentérica, junto con el hígado y páncreas, presentan un exceso de peso relativamente mucho mayor que el exceso del total. El estudio microscópico demostró un exceso aun mayor en la cantidad de tejido linfoide a lo largo del canal alimenticio (tónsilas palatinas y faríngeas, placas de Peyer y folículos solitarios). Las placas de Peyer eran tres veces mas grandes que lo normal y se hallaron numerosos folículos solitarios y acumulaciones linfoides mas pequeñas en el gato alimentado con la dieta mas rica en grasa, mientras que en el otro no se pudo hallar ningun folículo solitario. De estos datos el autor concluye que el tejido linfoide responde con marcadas diferencias en su cantidad a las diferencias en la dieta, consistentes en diferencias en el contenido de grasa y valor en calorias. Estos dos factores no han podido separarse aún.

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED BY
THE BIBLIOGRAPHIC SERVICE, NOVEMBER 1

THE EFFECT OF HIGH FAT DIET UPON THE GROWTH OF LYMPHOID TISSUE

EUGENE L. SETTLES

Anatomical Laboratory of the University of Missouri

SIXTEEN FIGURES (3 PLATES)

In spite of the universal interest in and the innumerable studies which have been made upon lymphoid tissue, very little has been learned regarding the factors which regulate its normal growth. It is known that lymphoid tissue is relatively much larger in amount during infancy and childhood and that it diminishes during adult life. It is also known that enlargement of lymphoid tissue may result from the effects of acute or chronic inflammation. However, the great variations in the lymphoid tissue, which are well known to occur, especially during childhood, form an unsolved problem.

Since the most important differences in the factors to which young animals are subjected are those associated with differences in diet, it seemed worth while to investigate the effect of varying diets on the amount of lymphoid tissue. The food element which seemed most likely to have a specific effect was thought to be fat, and for the following reasons.

Schäfer ('85, '12), who has made numerous studies on the relation between leucocytes and fat absorption, concludes from his own work and that of others that leucocytes, some varieties of which are formed in lymphoid organs, are known to take up fat in the villi and transport it to the lacteals.

Kischensky ('02), in studying the intestinal epithelium of young kittens during fat absorption, found leucocytes containing fat. From his description we may conclude that "these small round cells with large nuclei" are lymphocytes. He also found fat droplets in the macrophages of the lymph glands four to six hours after a meal.

E. R. and E. L. Clark ('17) observed that leucocytes are attracted to and actively ingest injected fat in the transparent tails of living amphibian larvae. Again, lymphocytes contain lipolytic ferment, while polymorphonuclears contain proteolytic ferment (Fiessinger and Marie, '09).

Czerny ('07) says that, with hypertrophy of fat in children, he finds enlargement of the tonsils, thymus, adenoids, and of the deep and superficial lymph glands, and that with regulation of diet in adiposity, he finds a diminution in size of lymphatic organs.

Hutinel (according to Steehman, '10) says that in acute intestinal inflammation after healing of the intestinal processes themselves there is a persistent emaciation of the child due to the disturbance of function of the mesenteric lymph glands. He also studied mesenteric lymph glands of dogs in different stages of digestion, and concluded that during digestion fat is emulsified in the mesenteric lymph glands and further worked over, and that here there must be a real chemical change. He says that the colorless content found in lymph vessels is soap. He also says that all the lymph glands play a similar rôle in inanition.

Poulain ('02) states that lymph glands play a double rôle in digestion, in that there occurs in lymph glands both splitting and synthesis of fat. He also says that during infection there is a lessened lipase activity of lymph glands and concludes that this may be the explanation of the general disturbance of nutrition which is found in intestinal infection.

Steehman ('10) investigated the question of relationship of lymph glands to fat digestion, and his conclusion is that the lymph glands are definitely concerned in the digestion of fat, and he states that they are assimilative organs for the fat derived from the tissues.

Bartel and Stein ('06) quote Paltauf, who holds that the enlargement of the thymus in status lymphaticus is not the cause of death, but merely a symptom of the general disturbance of metabolism further characterized by enlargement of the tonsils, lymph glands, and other lymphoid organs. He also describes fatty livers in many of these cases.

According to Kanthack and Hardy ('94), a meal causes a considerable rise in the number of lymphocytes in the blood. In rabbits, after a meal, they may form from 70 to 80 per cent of leucocytes, while in man two hours after a full meal they form about 30 per cent of the white blood-cells. These authors conclude that active digestion produces lymphocytosis, while starvation decreases the number of lymphocytes.

Thus, through the literature runs the strain of evidence that the lymphoid tissue plays an important part in the metabolism of fat.

It is well known that increase in the specific functions of tissues results in an increase in size. Hence, if lymphoid cells are concerned with absorption, transportation, and possibly with digestion of fat, one might expect the organs producing them to increase in size with an increase in the amount of fat handled by them.

As noted in the review of literature, the immediate effect of fat feeding has been investigated, and it has been found that the number of lymphocytes in the blood stream increases markedly during digestion, but shows a decided decrease in number during inanition. No definite reference, however, was found in the literature to any studies on the effect of a long-continued high fat diet on the size of lymphoid organs. It was therefore decided to plan experiments to test this question.

In addition to the general physiological and anatomical interest of this question, there are possible clinical applications of great importance. If lymphoid tissue is regulated to any considerable extent by the amount of fat given in the food, it follows that some of the enlargement of tonsils and adenoids in children may be due to a too high fat diet, particularly in those predisposed to this trouble by heredity.

The experiments reported here were begun with the idea of discovering the effect of an abnormal increase or decrease in the amount of fat in the diet upon the growth of lymphoid tissue. Milk was selected as the basis of the diet because of the ease of handling its fat content as well as for its general nutritional qualities. Kittens were chosen as suitable animals for the experi-

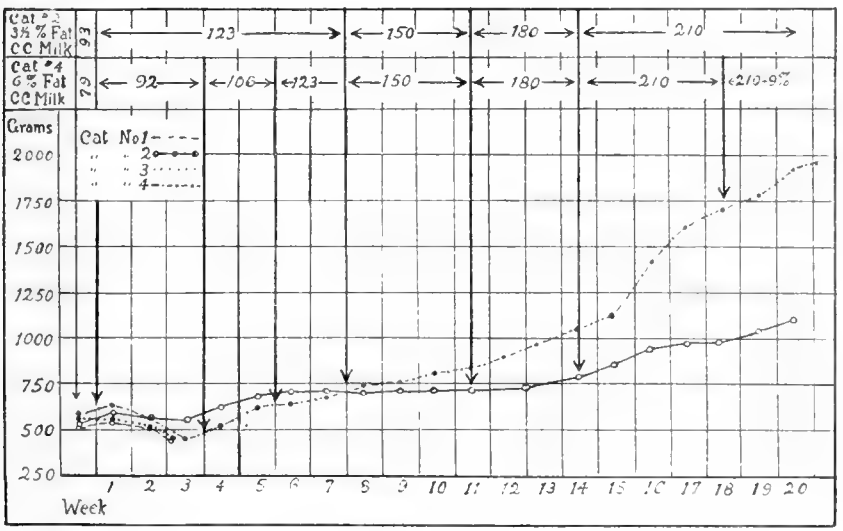
ment because of the possibility of feeding them at regular intervals and of controlling accurately the amount of food consumed at each meal. A litter of four kittens was obtained for the experiment. They were healthy animals, about three weeks old, and had not yet been weaned.

It was realized from the start that, if dependable results were to be secured, the animals would have to be attended to with greatest care, particularly as regards cleanliness of food, dishes, and cages, regularity of feeding, and mental condition. On account of the uncertainty of delegating such matters to a changing janitor force, it was decided from the start to feed and care for the animals personally. This was carried out from the beginning to the end of the experiment, except for short intervals when dependable substitutes were secured. The milk used was secured on alternate days from a reliable dairy and kept in clean bottles. During the warm weather the milk was kept on ice. The dishes were washed in hot water after each feeding. The floor of the cages consisted of wooden slats, the sides of fine-meshed wire. Water and a pan of sand were kept in each cage continuously, the sand being changed two or three times a week and the cages kept clean. Particular care was taken to keep the kittens free from all infections, parasites, or uncleanly conditions because of the possible effect of such agents upon lymph glands.

The kittens were fed the full amount of milk planned for them every day. At first they were fed three times a day, later twice a day, with an occasional day on which the total day's feeding was given at one time. The four kittens were kept in separate cages, with ample room for moving about. Throughout the entire experiment they were turned out of their cages frequently and allowed to play and exercise for an hour or more. They were treated kindly; in fact, they grew to be real pets.

Since no data were available as to the proper caloric requirement of young kittens, it was first necessary to determine the normal amount of milk consumed daily. A four-day test showed that the kittens consumed approximately 94 cc. of $3\frac{1}{2}$ per cent milk per 510 gram body weight or about 100 calories per kilo of body weight.

It was decided to feed the cats milk varying in fat content, as follows: no. 1, low fat, low calorie; no. 2, normal fat, normal calorie; no. 3, high fat, high calorie; no. 4, high fat, normal calorie. Based on the rough estimate mentioned above of 100 calories per kilo, the normal number of calories, and using $3\frac{1}{2}$ per cent fat as normal, the four cats were started on the diet shown in chart 1 The calorie contents, not shown in the chart, were: no. 1, 37.08 cal.; no. 2, 58 cal.; no. 3, 78.83 cal.; no. 4, 58 cal. The weights of the cats were, respectively, 510, 510, 538, and 510 grams.



This general plan was followed with increase in quantity once, until the death of cats no. 1 and no. 3. Thereafter, cat no. 4 was shifted to a high calorie diet, that is, it was given a daily amount of 6 per cent milk equal to the amount of $3\frac{1}{2}$ per cent milk given to cat no. 2. This was done in order to have a decided difference in the amount of fat given to the surviving cats.

The data concerning weight changes, amounts of milk given, with dates at which changes in amounts were made, are shown so fully in chart 1, that it is unnecessary to repeat them in detail. However, certain supplementary comments should be made.

On account of the difficulty of keeping the cats healthy on a pure milk diet, it was decided at the end of a week to give each cat a small amount of meat in order to keep them in good condition. Cat no. 2 received lean meat exclusively, while cat no. 4 was given meat containing small amounts of fat. The feeding of meat was continued throughout the remainder of the experiment, at two- or three-day intervals. This has been omitted from the chart. Changes in quantity were made whenever a stationary weight or increased greediness of the cats made it advisable.

A glance at the chart shows that none of the cats responded well to the change incident to weaning and confinement in separate cages. Instead of the rapid increase in weight which all animals of this age should show, there was a three-weeks period during which the weight remained stationary, as in cat no. 2, or declined, as in cats no. 1, no. 3, and no. 4. At the end of this period cats 1 and 3, which had been respectively on the low and high calorie diet, died, while cat no. 4 was in a very weakened condition. Although cat no. 2 appeared to be healthier than cat no. 4, still it maintained practically the same weight as at the start.

It is probable that the death of cats 1 and 3 and the poor condition of cats 2 and 4 toward the second of the third week were due to the change from mother's to cow's milk, accentuated in cats 1 and 3 by the markedly abnormal fat percentages.

After this, however, the condition of both cats no. 2 and no. 4 improved and continued excellent throughout the remainder of the experiment. From the third to the seventh week cat no. 2 increased slowly in weight. From the seventh to the twelfth week its weight remained practically stationary, even though the quantity of milk was increased at two different times. From the twelfth week to the end of the experiment its weight increased steadily, though slowly.

After the end of the third week when cat no. 4 almost died, it apparently adjusted itself to the high fat diet and began to gain weight, until, at the eighth week, its weight exceeded that of cat no. 2. From this time on until the end of the experiment the rate of gain of cat no. 4 was much more rapid than of cat no. 2.

During the last two weeks of the experiment, an attempt was made to increase still further the amount of fat consumed by cat no. 4, consequently 9 per cent milk was given during this period. However, during the first few days following this final change in diet, the cat did not drink the full quantity of milk. During the last week it accustomed itself to this extremely high fat percentage and at the time when the animals were killed it was consuming the entire amount of milk offered.

Cat no. 4 was killed on February 11th, nineteen weeks and three days after the beginning of the experiment. Cat no. 2 was killed two days later, at the same time of day as no. 4 and at exactly the same interval of time after the last feeding. The autopsies will be given later.

The history of the experiment, as represented graphically in the chart, shows that the original experiment of feeding four kittens of the same litter had be to modified owing to the death of two of the cats at a period before any of the four had become adjusted to cow's milk and confinement. Cat no. 2 received the same diet throughout, as regards fat percentage, and the amount of diet was determined by the natural appetite of the animal. While its growth was much slower than normal so that the total weight and size of organs cannot be considered normal, nevertheless it serves as a satisfactory control as regards the effect of differences in fat content of the diet. Cat no. 4, starting out with a diet of 6 per cent milk containing the same number of calories as the control animal, after the death of cat no. 3, was given the same quantity of 6 per cent milk as that of the $3\frac{1}{2}$ per cent milk fed to cat no. 2, hence it received a greater number of calories. During the latter half of the experiment this cat received some fat meat while cat no. 2 received nothing but lean meat. During the last few days of life, cat no. 4 was consuming the amount of 9 per cent milk equivalent to the quantity of $3\frac{1}{2}$ per cent milk taken by the control. Hence cat no. 4 was fed a high fat diet throughout the experiment, and after the fifth week it received a high calorie as well as a high fat diet.

The cats, as has been stated, were kept clean and free from parasites throughout the experiment, with the exception of a

small number of fleas which appeared at times and were treated with insect powder. The general condition of both was excellent during the last fifteen weeks.

AUTOPSIES

Cats no. 1 and no. 3

Owing to the fact that cats nos. 1 and 3 had failed to adapt themselves to cow's milk and had been in an increasingly weakened condition for several days before they died, it was thought that little would be gained from extensive study of the lymphoid organs. Careful autopsies showed nothing markedly abnormal in the thoracic and abdominal organs. The large mesenteric lymph gland from each cat was weighed and examined microscopically. The weight of the gland from cat no. 3, 1.470 grams, exceeded that from cat no. 1, 1.423 grams, by 0.047 gram. Microscopic examination, however, showed a definitely larger number of lymphoid cells making up the cortex and medullary cords and filling the sinuses in cat no. 3 as compared with cat no. 1.

Cats no. 2 and no. 4

As previously mentioned, both these cats were in perfect health at the end of the experiment; their coats of fur were smooth and silky and they were active and playful. Cat no. 4, which had been fed the high fat diet, was larger and heavier and conspicuously fatter than cat no. 2, which had received a normal percentage of fat. The two cats were killed at exactly the same hour of the day and at the same length of time after the last feeding.

Autopsy of cat no. 4 (male). Cat was killed with chloroform February 11th at 9:50 A.M. The last feeding was given at 2:30 P.M., February 10th. There is a layer of subcutaneous fat over the abdomen, about one-quarter of an inch thick. Much fat is present in the omentum. The peritoneal, pleural, and pericardial surfaces are smooth and shiny, with no increase in fluids in these cavities. The lacteals are well injected with fat. The

chief mesenteric lymph gland is homogeneous in appearance and seems large and swollen. It weighs 3.040 grams. The other small, scattered mesenteric lymph glands were not noticeably increased in number. The stomach and intestines show nothing abnormal from the outside. On opening, the stomach is found to contain a considerable amount of partly digested material and the small intestine much yellowish semisolid material. No worms or other parasites were visible to the naked eye in stomach or intestine. The mucous membranes showed no especial reddening or other abnormality.

In the lower part of the ileum, the Peyer's patches (folliculi agminati) stand out with exceptional clearness. They form mottled raised areas projecting into the lumen of the bowel clearly marked out from the surrounding mucosa. The largest patch is the one in the terminal ileum, just above the ileocecal valve, which measures 3 cm. in length. In the 12 cm. of intestine anterior to this there are four round patches, each about 1 cm. in diameter, all conspicuously raised over the surrounding surface. The pancreas is large and normal in appearance, weighing 9.055 grams. The spleen is dark red with numerous white spots, and has rounded edges. It weighs 3.060 grams. The liver is very large with rounded edges, and has a yellowish color. It weighs 118 grams. The right and left kidneys are dark red in color, showing nothing abnormal. Their weights are 6.5 and 6.7 grams, respectively. The lungs are air containing and normal, save for one small atelectatic area in the upper right lobe. The heart is surrounded by a considerable amount of fat. It shows nothing abnormal. Its weight is 7.9 grams. One each of the right bronchial and right inferior cervical lymph glands were examined and preserved. They show nothing unusual macroscopically. The thymus is homogeneous in appearance and seems unusually large. It weighs 5.495 grams. The right and left tonsils are covered with hemorrhagic spots. In order to preserve them without injury for histological study, some of the surrounding tissue was dissected out with them, therefore it was not possible to estimate their weight accurately. The pharyngeal tonsil which is located at the top and posterior wall of the pharynx, is

easily seen as a definitely raised area containing many raised whitish translucent spots. The left femur was preserved. It weighs 6.557 grams, while its greatest length is 7.8 mm. The left tibia was also preserved. Its weight is 5.200 grams and the greatest length is 83 mm. Most of the subcutaneous fat was dissected out. It weighs 109.4 grams. Either all or parts of the various organs were preserved in Zenker's fluid for microscopic study.

Autopsy of cat no. 2 (male). Cat was killed with chloroform, February 13th at 9:20 A.M. The last feeding was given at 2:30 P.M., February 12th. There is little fat present over the abdomen. The omentum likewise contains little fat. There is no increase in the fluid in the pleural, pericardial, or peritoneal cavities. Linings of all these cavities are smooth and shiny. The lymphatics are filled with chyle. The chief mesenteric lymph gland is homogenous in appearance. Its weight is 1.990 grams. The stomach and intestine show nothing abnormal externally. On opening, the stomach is found to contain a small amount of nearly digested food and the small intestine contains very little except some brown mucus. No worms or parasites were visible to the naked eyes in the stomach or intestine. The mucous membranes are apparently normal. On opening the lower end of the ileum, it is found to be practically empty. A long Peyer's patch is found here. It is scarcely raised above the general epithelial surface and its extent is difficult to determine. The remainder of the small intestine was searched carefully for other Peyer's patches, but none could be seen in the gross specimen. The presence of the brown mucus here possibly prevented us from discovering the smaller patches at the time; however, the entire small intestine was preserved for further examination. The pancreas shows nothing abnormal. It weighs 5.540 grams. The spleen has sharp, definite edges and its surface is mottled with small round nodules. It weighs 2.470 grams. The liver is normal apparently; it is dark red in color and has sharp edges. Its weight is 60.9 grams. The right and left kidneys are normal in appearance, weighing 5.1 and 5.3 grams, respectively. The right lung shows a small atelectatic area, otherwise both lungs are

normal. The heart is normal, weighing 6.5 grams. The thymus is very pale. It weighs 2.973 grams. The largest right inferior cervical lymph gland shows nothing abnormal macroscopically. It is very pale in color. At the roof of the pharynx in the place where the pharyngeal tonsil was easily seen in cat no. 4, only a faint mottling can be seen. On dissecting this tissue loose from the bone and examining it carefully, definite small nodules may be seen. The left femur was preserved. It weighed 4.870 grams and its greatest length was 67.5 mm. The left tibia was also preserved. Its weight is 3.607 grams and its greatest length 73 mm.

DISCUSSION OF AUTOPSY FINDINGS OF CATS NO. 2 AND NO. 4

The postmortem examination confirmed the observations of the living animals that the two animals were entirely free from disease. It is noteworthy that no parasites were found.

The difference in the weight of these two animals at the time of death has already been referred to. It was obvious merely from the superficial inspection at the time of autopsy that the subcutaneous fat, the fat in the omentum and around the heart was noticeably greater in the cat which had received the high fat diet. Moreover, the macroscopic appearance of the liver, with its rounded edges and yellow color, made it appear highly probable that the difference in the weight of this organ in the two cats was due to an extra fat content in cat no. 4. (This was later confirmed by histological findings.) Aside from these differences in stored fat, the most noticeable difference in the two cats was found in the lymphoid tissue. Even without the comparison of the weights of the different lymphoid organs, the greater size of those in the fatter cat was very apparent. This was especially noticeable in the case of the Peyer's patches. In the cat fed on high fat diet, the Peyer's patches were large, discrete, conspicuous, and prominently raised above the intestinal wall, while those of the cat fed on normal fat percentages were scarcely raised above the epithelial surface and so inconspicuous as to make their detection very difficult from macroscopic examination. The same contrast, in somewhat less degree, was noticeable in the case of the pharyngeal tonsils. The lymphoid tissue

in the pharynx of cat no. 4 was fairly thick and well raised above the surface, while in this same region in cat no. 2 the lymphoid tissue was represented merely by a faint mottling of the roof of the pharynx.

The comparison of a number of the organs of the two cats is best brought out by a chart showing the weights. These weights were all obtained in the fresh state.

Chart 2 gives the weights of the larger lymphoid organs (such as mesenteric lymph glands, thymus, spleen, etc.) of the two cats and also the weight of other organs (such as the heart, kidney, liver, etc.) for the sake of comparison. The smaller lymphoid organs, such as the Peyer's patches, the palatine tonsils, cervical lymph glands, and pharyngeal tonsils, could not be accurately weighed on account of the necessity of leaving some of the surrounding tissue attached to them, hence the comparison of these was based upon microscopic study.

In chart 2, the weights of the two cats and the absolute and relative weights of their various organs are first given. The excess body weight of cat no. 4 over cat no. 2 is next shown, together with the excess weight of its various organs.

For several reasons the body weight of cat no. 4 should be corrected, in order to obtain a fair comparison of the various organs. It has been mentioned that 109.5 grams of subcutaneous fat was found in cat no. 4, while cat no. 2 had very little subcutaneous fat. Again, the liver of cat no. 4 proved to contain an enormous amount of stored up fat. Beside these two factors, the gastro-intestinal contents were much greater in cat no. 4 than in cat no. 2. Now it would seem that the organs which would give the best relative comparison between animals such as these two cats at the end of the experiment would be the heart, kidneys, and perhaps the skeleton. On obtaining the average of the percentages by which cat no. 4 exceeds cat no. 2 with respect to heart, kidneys, tibia, and femur, the result arrived at is approximately 30 per cent. This same figure is obtained approximately if the excess subcutaneous fat (109.5 grams) plus a portion of the liver weight (37.5 grams), which accounts for only part of the stored-up fat, be subtracted from the gross body weight

CHART 2

Absolute and relative weights of body and organs, cat no. 2 and cat no. 4

ALL WEIGHTS GIVEN IN GRAMS	TOTAL BODY	THYMUS	SPLEEN	MESENT. LYMPH GLAND	LIVER	PANCREAS	LEFT TIBIA	LEFT FEMUR	HEART	RIGHT KIDNEY	LEFT KIDNEY
Cat no. 2 (3½ per cent fat), absolute weight....	1219	2.973	2.470	1.990	60.9	5.540	3.607	4.870	6.50	5.10	5.30
Cat no. 2, per cent of body weight.....		0.24	0.2	0.16	5.0	0.454	0.296	0.40	0.533	0.418	0.434
Cat no. 4 (6 per cent fat), absolute weight.....	1729	5.495	3.060	3.040	118.0	9.055	5.20	6.557	7.9	6.5	6.7
Cat no. 4, corrected weight.....	1582										
Cat no. 4, per cent of corrected body weight.....		0.35	0.19	0.19	7.46	0.572	0.329	0.414	0.50	0.41	0.423
Excess weight, cat no. 4 over cat no. 2.....	363[1]	2.522	0.592	1.050	57.1	4.515	1.593	1.687	1.4	1.4	1.4
Per cent excess, cat no. 4 over cat no. 2.....	30[1]	84.8	23.8	52.7	93.7	80.6	44.1	34.6	21.1	27.4	26.4
Difference between excess per cent of organs and excess per cent of corrected body weight.....		+54.8	—6.2	+22.7	+63.7	+50.6	+14.1	+4.6	—8.9	—2.6	—3.6

[1] For these figures the corrected weight of cat no. 4 is used.

of cat no. 4. Thus, subtracting 147 from 1729, the resultant figure 1582 is obtained as the corrected weight of cat no. 4, which is 363 grams, or 30 per cent in excess of the weight of cat no. 2. Were the excess gastric and intestinal contents also subtracted, the figure would probably be lowered to about 25 per cent, which is about the average by which the heart and kidneys of no. 4 exceed no. 2. However, for safety, the figure 30 per cent is chosen for the table.

With this new percentage excess as a basis, the percentage excess of the various organs of cat no. 4 over cat no. 2 are calculated. By this means a truer estimate is arrived at of the actual effect of the difference in diet on the individual organs.

It is seen from the corrected percentage table at the bottom of chart 2 that the organs may be divided into three groups:–1) those apparently affected by the difference in diet, i.e., the liver, the thymus, pancreas, and mesenteric lymph gland; 2) those which may have been affected by the difference in diet, i.e., femur and tibia, and, 3) those which were apparently not affected by the difference in diet, i.e., the kidneys, spleen, and heart. Discussion is reserved until the microscopic findings have been given.

MICROSCOPIC STUDY OF ORGANS FROM CATS NO. 2 AND NO. 4

The various organs were fixed in Zenker's fluid for the most part. They were dehydrated in graded alcohols and aniline oil, cleared in xylol, imbedded in paraffin, and sectioned at 10 μ or 15 μ. Since this technique proved to be unsatisfactory in the case of the thymus, portions of this organ were imbedded in celloidon. Bouin's fixative and the method of dehydration described by Allen ('19) were also tried, but the tissues treated in this way proved to be too hard to section well. The sections were stained with Mayer's haematoxylin and eosin. The attempt was made, in each case, to secure specimens and sections from the two cats which corresponded as exactly as possible, as regards the part of the organ from which they were taken, the plane of sections, and the technique employed.

The chief object of the microscopic study was to find out the difference in the amount of lymphoid tissue in the lymphoid organs of the two cats. Measurements with the micrometer eyepiece were made of the sections of the different lymphoid organs of the two cats. However, the wide variation in the shape of these organs in the two cats and the uneven distribution of the lymph follicles and cords as well as the varying sizes and distribution of vessels, connective tissue, and spaces in the organs of the two cats make this method rather unreliable. The most satisfactory comparisons were derived from observation of the sections and from microphotographs taken at the same magnification.

Liver. The liver of cat no. 2 (control) is apparently normal histologically. In contrast to this, the liver of cat no. 4 (fed on the high fat diet) is packed with fat globules of various sizes to such an extent that the whole liver structure is altered and its regularity destroyed. The cell structure is also changed by reason of the stored fat. The liver cells present a spongy appearance due to the presence in them of fat globules of various sizes. In many places the fat globules are so large that it is difficult to determine whether they are inside the liver cells or whether they are intercellular.

The microscopic findings in the liver of cat no. 4 adequately explain the differences noted in the gross specimens of the two cats, especially the immense difference in the weight of the two organs.

Pancreas. No significant histological difference was found in the case of this gland from the two cats.

The microscopic study of the lymphoid organs will now be considered.

Cervical lymph gland. The variability in shape and size of lymph glands makes comparison of the smaller glands unsatisfactory. Fortunately, the cat possesses an enormous mesenteric lymph gland, on which comparisons of size are feasible. The cervical glands, one from each cat, are selected as samples of smaller glands and are to be compared merely as regards relative distribution of lymphoid tissue, as seen with the microscope.

While the cortex of the gland from cat no. 2 is wider at one point than the cortex of that of cat no. 4 at its widest point, a glance at the figures of the two glands (figs. 1 and 2) shows that this gives an erroneous idea of the comparative amount of cortical substance present in the two glands. In cat no. 4 the cortex maintains a fairly even thickness throughout the entire circumference— a thickness which in no place falls far below the maximum. In cat no. 2 the cortical substance is either missing entirely or very narrow over approximately two-thirds of the circumference, being present only as two separated masses at the two ends of the section. Recognizable follicles are present in both glands. They are more numerous in the gland from cat no. 4, in which they are arranged fairly regularly around the circumference of the gland, with an occasional follicle more deeply placed. In the medulla of cat no. 2 the cords are narrow and somewhat irregular, but in cat no. 4 they are much wider and more continuous. The sinuses contain many more lymphocytes in the gland from cat no. 4 than in that from cat no. 2.

It is clear, from the comparison of the glands, that there is a definitely greater amount of lymphoid tissue in the gland of cat no. 4 than in that of cat no. 2.

Pharyngeal tonsils. As may be seen in figure 4, a cross-section of the pharyngeal tonsil of cat no. 2, the lymphoid cells are somewhat sparsely distributed in the reticulum. Two definite large solitary follicles are present. The lymphoid cells are more closely packed around the edges of these follicles than at any other place in the section. In the centers of the follicles the lymphoid cells are somewhat grouped together, leaving definite clear spaces between.

In the pharyngeal tonsil from cat no. 4, figure 3, the lymphoid cells are much more closely packed together. The solitary follicles are crowded with lymphoid cells. There is a much larger amount of lymphoid tissue outside the follicles than in the gland of cat no. 2, and the lymphoid cells here are more closely packed together.

The measurements of the lymphoid tissue of a typical cross-section of the pharyngeal tonsils are as follows:

Cat no. 2, greatest length, 3.5 mm.; greatest width, 0.52 mm.

Cat no. 4, greatest length, 5 mm.; greatest width, 1 mm.

The approximate areas of the cross-sections are: Cat no. 2, 1.82 sq.mm., and cat no. 4, 5 sq.mm. Since the sections are through comparable parts of the glands and since care was taken to secure exact cross-sections, these figures give a rough estimate of the relative volumes of the two glands, namely, a proportion of 1 to 2.7. In view of the relatively greater density of the lymphoid cells in the gland from cat no. 4, it is probable that the pharyngeal tonsil from cat no. 4 contains in the neighborhood of three times as much lymphoid tissue as that from cat no. 2.

Palatine tonsils. A comparison of these is somewhat unsatisfactory, owing to the difficulty of orienting them for obtaining corresponding sections. However, since their oval shape makes possible a cross-section perpendicular to the long axis, and by selecting the sections through the largest part of each gland, a fair comparison is secured. Two such sections, pictured in figures 5 and 6, show the following.

The section from cat no. 2 (fig. 6), is oval in shape. There is a narrow open space in the middle, which represents the crypt which extends deep into the gland.

Twelve solitary follicles may be counted arranged in a single marginal layer. The periphery of the follicles as well as the spaces between follieles are densely packed with lymphoid cells. Bordering the crypt, lymphoid cells are more densely packed than in the surrounding area.

In the section from cat no. 4 (fig. 5) the crypt is shown extending to the surface. There are twice as many follicles—twenty-four—as in the gland from cat no. 2, and they occur in two and three layers. The epithelium lining the crypt is invaded and, in many instances, largely replaced by lymphoid cells, which form a dense area near the lumen. The distribution of lymphoid cells is about the same as in cat no. 2.

Measurements of sections of the two glands are as follows:

Cat no. 2, greatest length, 3.4 mm.; greatest thickness, 1.8 mm.

Cat no. 4, greatest length, 5.4 mm., greatest thickness, 2.5 mm.

The areas of the two sections are in approximately the ratio of one to two for the sections from cats no. 2 and no. 4, respectively.

Although these are only rough approximations of the size of the gland, all the data point to the gland from cat no. 4 as being very decidedly—probably at least 100 per cent—larger than the gland from cat no. 2, which, with a similar relative distribution of lymphoid cells, means a decidedly greater total amount of lymphoid cells in the cat receiving the higher fat diet.

Spleen. The sections shown in figures 9 and 10 are taken from the widest portions of each gland. In the section from cat no. 2 (fig. 8) a considerable number of red blood-cells may be seen scattered among the lymphocytes and other cells. The lymphoid cells are numerous and evenly distributed. The malpighian corpuscles are rather small and contain definite germinal centers. The section from cat no. 4, figure 7, contains a greater number of red blood-cells. The malpighian corpuscles are more numerous than in cat no. 2 and definitely larger. The germinal centers have about the same appearance as in cat no. 2, possibly not as distinct.

It will be remembered that there was very little difference in the weight of the two spleens, considering the difference in the size and weight of the two animals. The microscopic study, however, shows a slight difference in the lymphoid tissue in the two cats. The spleen of cat no. 4 contains perhaps slightly more lymphoid tissue than that of cat no. 2, due to the increased number and definitely larger size of the malpighian corpuscles. However, the difference is hardly enough to justify the conclusion that the spleen has been modified by the difference in diet.

Thymus. Figures 9 and 10 show the thymus gland of cat no. 4, and no. 2, respectively. These typical sections are very difficult to compare microscopically, owing to the great difference in the shape and arrangement of the lobules. Moreover, a comparison of the relative size of the medulla and cortex in the lobules is inaccurate as the section goes through the different lobules at different levels.

In the section shown from cat no. 2 some of the lobules show a definite demarcation between cortex and medulla, while others show none, according to the part of the lobule cut through in the

section. The cortex of the lobules is densely packed with lymphoid cells, the medulla being comparatively free from them. In the section of thymus from cat no. 4 there are clearly more large lobules present than in cat no. 2. Whether the total number is greater is very difficult to say, owing to the irregularities in size and shape. There is little difference in the relation of cortex to medulla in cat no. 4 as compared with cat no. 2. The place in the lobule through which one section passes affects this relationship, as in cat no. 2.

Apparently, then, the most important point in the microscopic comparison of the thymus of cat no. 2 and the thymus of cat no. 4 is the larger size of lobules found in the latter. Since the total weight shows a percentage excess for the thymus from cat no. 4 of 54.8, as shown in chart 2, and since the microscopic study shows lymphoid tissue to form at least an equal percentage of the entire gland, there is an excess percentage of lymphoid tissue of at least 50.

Mesenteric lymph glands. The sections were taken through the enlarged part of the glands, at which place they were of about the same diameter. Both glands at this point contain two definite lobes, separated by connective tissue.

Figures 11 and 12 show sections of the two larger lobes of cat no. 4 and no. 2, respectively. These two lobes are about the same size. In the section from cat no. 4 we notice a decidedly great number of solitary follicles which are also larger and show a thicker and denser rim of lymphoid cells, as compared with the gland from cat no. 2. In cat no. 4 these follicles are found in the medulla as well as in the cortex. Few are seen in the medulla of the gland of cat no. 2. The cortex of cat no. 4 apparently contains more lymphoid tissue than that of cat no. 2, but the difference is not great. However, the most striking thing about the sections is the comparison of the medulla. There is in cat no. 4 a greater area of medulla than in cat no. 2. The cords in the medulla are greater in number and decidedly larger and more continuous. Likewise, the sinuses cover a greater area and contain a great many more lymphocytes in the gland from cat no. 4 than are found in cat no. 2, where the sinuses are comparatively

free from lymphocytes. The two smaller lobes of cat no. 2 and cat no. 4 compare in practically the same way as the larger lobes.

The comparison of these two typical sections, then, shows but little difference in the comparative area occupied by lymphoid cells in the two glands. The medullary cords are larger and the follicles are larger and more densely packed with cells at the periphery in cat no. 4 than in cat no. 2. However, the extrafollicular accumulations of lymphoid tissue are perhaps greater in cat no. 2. Other sections of these glands were studied and showed similar conditions. Since, however, the gland from cat no. 4 showed a percentage weight which was 22.7 per cent higher than that from cat no. 2, it is obvious that the percentage amount of lymphoid tissue present in the mesenteric lymph gland of cat no. 4 exceeds that of cat no. 2 by at least 22.7 per cent.

Peyer's patches (agminated follicles). By far the most striking difference found in any of the lymphoid organs was that found in the comparison of the Peyer's patches, as seen through the microscope. Cross-sections of the long patch located in the terminal portion of the ileum are shown in figures 13 and 14 and parts of them shown again at a higher magnification in figures 15 and 16.

A comparison of the dimensions of the cross-sections is as follows:

Width of patch, cat no. 4, 7.5 mm.; cat no. 2, 5.2 mm. Average thickness of patch, cat no. 4, 2.2 mm.; cat no. 2, 1.04 mm.

Since this patch has been found in several cats to be of approximately the same length and of fairly uniform width, it is possible to estimate, from the two dimensions given, the relative volumes of the Peyer's patches in cats no. 2 and no. 4. The areas of the cross-section are found to be: for cat no. 4, 16.5 sq.mm.; for cat no. 2, 5.4 sq. mm. It follows that the volume of the gland from cat no. 4 is three times the volume of the gland from cat no. 2. This is a far greater difference than has been found in any of the organs in which comparison by weight was possible. Moreover, a study of the sections shows an equally striking difference in the histological picture. The section from cat no. 2 shows a row of nine follicles, lying mainly between the muscularis mucosae

and the circular muscle layer, with a fairly wide stretch of submucosa intervening between the follicles and the latter. Toward the lumen, these follicles have projections, most of which end at the muscularis mucosae. A few of them break through this layer and extend out into the base of the villi, forming wedge-shaped structures. Between the follicles there is some lymphoid tissue in the half of the patch toward the lumen, while in the other half there is loose tissue. The villi over the patch are, in the main, normal appearing, save for the few whose bases are invaded by the wedge-shaped lymphoid projections, though perhaps they are slightly shorter than over the remainder of the mucosa.

The section from cat no. 4 shows extraordinary differences. There is about an equal number of follicles, but the individual follicles are enormously larger — in fact, as seen in figures 15 and 16, they may well be called gigantic — as compared with those from cat no. 2. The space at the submucosa between the follicles and the circular muscle layer is somewhat less than in no. 2. The follicles are packed with lymphoid cells. Toward the lumen, the muscularis mucosae is broken through at many more places than in no. 2, and the wedge-shaped projections into the villi are much larger and more numerous. The villi over the patch are very short and wide, many containing a central mass of lymphoid tissue. The spaces between adjacent follicles are smaller than in no. 2, and are filled with lymphoid tissue in the half toward the lumen, as in cat no. 2.

It is obvious that the proportion 1 to 3, found for the volumes of the patches, probably underestimates the relative amounts of lymphoid tissue, since the follicles are equally packed, while in no. 4, the projections through the submucosa are much greater and the spaces between the follicles much less.

A very suggestive finding, also, was that of the presence on cat no. 4 of isolated follicles, separated from the Peyer's patch, usually one or two in each section. None were found in cat no. 2. This suggested that new follicles may have developed in cat no. 4 and led to a study of the lower ileum to determine how extensive this difference might be.

Solitary follicles and lymphoid accumulations in the lower ileum. In order to obtain an estimate of the relative number and size of solitary follicles in the lower ileum, five blocks of intestinal tissue from cat no. 4 and six from cat no. 2 were examined. The pieces, $\frac{1}{2}$ to 1 cm. long, were taken at various corresponding levels, from the lower third of the small intestine. The blocks were embedded in paraffin and cut transversely into sections 25 μ thick. Every fifth section was saved. The results are as follows:

Cat no. 4: block (1) 38½ cm. above caecum in	35 sections	6	solitary follicles
Cat no. 4: block (2) 25½ cm. above caecum in	29 sections	19	or lymphoid
Cat no. 4: block (3) 20½ cm. above caecum in	25 sections	17	accumulations
Cat no. 4: block (4) 16 cm. above caecum in	45 sections	35	
Cat no. 4: block (5) 11 cm. above caecum in	42 sections	61	
Total	176 sections	138	
Cat no. 2: No. (1) 39 cm. above caecum in	63 sections	0	solitary follicles

In estimating the number of follicles in cat no. 4, follicles appearing in more than once section were counted once only. Peyer's patches seen in some of the blocks from both specimens were disregarded.

The 'follicles' seen in cat no. 4 vary from small accumulations of lymphoid cells, located outside the muscularis mucosae, to full-sized follicles, many of which project through the muscularis mucosae into the base of the villi.

The result of this estimation is most striking. In the intestine of cat no. 2, 324 sections were examined, and no trace was found of lymphoid accumulations or solitary follicles, apart from Peyer's patches. In cat no. 4, in only a little more than half as many sections, 138 separate lymphoid accumulations or solitary follicles were seen, in addition to Peyer's patches. This result is the most striking one which has been obtained and harmonizes with the study of the two Peyer's patches. There can be no question

but that the difference in diet is an exceedingly important factor in the regulation of the amount of lymphoid tissue in the intestinal wall.

DISCUSSION AND CONCLUSION

In reviewing the results of the experiments, it should be emphasized that whatever effect may have been produced by the difference in diet cannot be attributed unequivocally to the mere difference in the fat content of the diet, since there was also a difference in the amount of calories. The experiment, therefore, shows the effect of a high calorie diet, in which the excess calories are provided by the fat of cow's milk. With this definitely understood, let us group together the results which have been obtained.

A comparison of the weights of organs has shown that there has been produced, in the animal receiving the richer diet, an enlargement of pancreas, liver, thymus, and mesenteric lymph gland out of proportion to the enlargement of other organs, such as heart and kidneys. Gross appearance and the study of microscopic sections have also shown a striking enlargement of the lymphoid tissue along the digestive tract—of the palatine and pharyngeal tonsils and especially of the Peyer's patches and solitary follicles. Microscopic study and comparison of the elements making up the lymphoid organs showed the lymphoid tissue to be either equally extensive or more extensive, relatively, in the cat fed the high calorie, high fat diet as compared with the control. The excess weight and size were found to be due not to stored-up fat (except in the liver), but to increase in lymphoid tissue proper. Therefore, it is obvious that, in lymph gland and thymus, with a decided excess in weight, and at least an equal distribution of lymphoid tissue, the high calorie, high fat diet has resulted in a very substantial increase in the amount of lymphoid tissue proper. In the two tonsils and particularly in the Peyer's patches, all of which are made up of practically solid lymphoid tissue, the difference in size as seen in corresponding sections and which amounts, in the case of the Peyer's

patches, to a 200 per cent excess indicates a decidedly larger relative amount of lymphoid tissue as a result of the higher diet.

An exception is furnished by the spleen, which though a lymphoid organ, shows no excess weight nor any marked increase in lymphoid tissue proper. It might be urged, in explanation, that the spleen is extremely variable in size in normal animals, as has been pointed out by Mivart ('98) and Hatai ('15), among others, and that a larger number of experiments might yield a result different from the present single experiment. However, this would be unjustifiable, considering the similarity of treatment of the two animals. It is only fair to conclude that the size of the spleen and the amount of lymphoid tissue contained in it have not been affected by the difference in diet.

The very great excess increase in the thymus is of extreme interest. It has been found by many observers that the thymus is remarkably sensitive to undernourishment. Its response is so striking that Hammar ('05) has given the name 'accidental hunger involution' to the great reduction in size which occurs. Jonson ('09) found in rabbits, after four weeks of underfeeding, a reduction in weight of thymus to one-thirtieth the weight of the control. Jackson ('15) observed a loss of 90 per cent relative weight in the thymus of rats given a maintenance diet between the ages of three and ten weeks. Stewart ('18) obtained, in rats held at maintenance diet from birth to ten weeks, an 80 per cent loss in relative weight of the thymus. Jonson ('09) found an extremely rapid recovery rate on resumption of normal feeding, normal weight being reached after three weeks of normal diet following a period of undernourishment.

The present study indicates that the thymus responds to a surplus diet, in which the surplus calories are supplied by fat, by a decided increase in size. It thus supplements and supports previous studies which shows the thymus to be particularly sensitive to differences in diet.

The similarity in response of the thymus and of the lymph glands and lymphoid tissue along the intestinal tract affords evidence in support of the theory that the thymus should be grouped with lymphatic glands as a lymphoid organ.

The results furnish new evidence in support of the view, suggested at the beginning of the paper in the review of literature, that the lymphoid organs are concerned with metabolism—probably with fat metabolism for they show a marked response to the high fat diet, along with the liver and pancreas, which are known to be specifically concerned with the storage and digestion of fat. In responding to an increased function, or demand, for lymphoid cells, or lymphocytes, by an increase in size, the lymphoid organs would be merely following the well-proved law of functional adaptation, according to which increase in the function of an organ is accompanied by increase in size.

Further studies should be made in order to analyze the two factors of high calorie and high fat, which have been combined in the present experiment, and also to test the effect on lymphoid organs of other dietary factors. However, whether the results have been caused by one or the other, or both, they are of value, for they show that these organs respond very decidedly to differences in diet, by differences in size, which are far out of proportion to the relative differences in the size of the entire animals.

SUMMARY

Four kittens of the same litter and practically the same weight were fed on diets differing in fat content, with the purpose of discovering the effect of a high fat diet on lymphoid tissue.

Two of the animals, one of which had been fed on a low fat percentage (0.7 per cent) and the other a high fat percentage (6 per cent), died at the end of three weeks. No appreciable difference was found in the gross appearance or weight of the lymphoid tissue of these two cats. However, microscopic examination showed a noticeably greater amount of lymphoid tissue in the mesenteric lymph gland of the cat which had received the high fat diet.

The other two kittens were kept for a period of four and one-half months, one on a normal fat percentage diet (3½ per cent) and the other on a high fat percentage diet (6 per cent). They both remained in perfect health throughout the last three and a half months of this time.

Although the two cats started with the same size and body weight, at the end of the four and a half months the cat fed on higher fat diet weighed 510 grams more than the control, and was practically 30 per cent larger, excluding the amount of stored fat present.

In the cat fed on a high fat percentage diet, the organs known to be concerned with fat metabolism and storage (the pancreas and liver) were noticeably larger, both by actual weight and percentage than in the control specimen.

In addition, the lymphoid tissue, with the exception of the spleen, was noticeably heavier in the cat receiving the high fat diet, the excess amounting to a difference of 85.8 per cent in the case of the thymus and 52.7 per cent in the case of the mesenteric lymph gland.

In contrast to this, the heart and kidneys were only about 25 per cent larger in the larger animal.

Microscopic examination of similar cross-sections from all the lymphoid organs of the two animals showed either an equal or a greater amount of lymphoid tissue per unit area in the cat which had been fed on the high fat diet. The difference was most strikingly shown in the case of the Peyer's patch and the solitary follicles in the intestine.

It is pointed out that the results obtained indicate that a combined high fat, high calorie diet produces a general enlargement of the lymphoid tissue of the body, which is most strikingly seen in the lymphoid tissue of the gastro-intestinal tract, but that they do not differentiate between the two factors -high calorie and high fat. An analysis of these two factors as well as the effect of other food elements should form the subject of further investigations.

My sincerest thanks are due Dr. E. R. Clark for his invaluable advice and interest in the problem here presented.

EXPLANATION OF FIGURES

Figures 1 to 16 are microphotographs of histological sections of organs from cats no. 2 and no. 4. They are arranged in pairs—in each case the even numbers (2, 4, 6, etc.) placed at the right, being taken from the organs of cat no. 2, the odd numbers (1, 3, 5, etc.) at the left, from cat no. 4. The two pictures shown in each pair were taken at exactly the same magnification. The enlargement varies for the different pairs. The two pairs shown in figures 15 and 16 show, at a higher magnification, parts of the same sections as are shown in figures 13 and 14, respectively.

Resumen por el autor, Ivan E. Wallin,
University of Colorado.

Un caso de persistencia de la vena supracardinal izquierda con dos venas espermáticas izquierdas.

La descripción de este caso consiste principalmente en una ilustración de las variaciones venosas del sujeto estudiado. La porción inferior de la vena cava inferior consta de dos troncos. La vena espermática izquierda esta representada por dos vasos distintos; uno de ellos comunica con la vena renal y el otro con la vena supracardinal izquierda, que persiste en este caso.

Translation by José F. Nonidez

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED
BY THE BIBLIOGRAPHIC SERVICE, NOVEMBER 15

A CASE OF PERSISTENT LEFT SUPRACARDINAL VEIN WITH TWO LEFT SPERMATIC VEINS

IVAN E. WALLIN

Department of Anatomy and the Henry S. Dennison Research Laboratories, University of Colorado

ONE FIGURE

The occurrence of duplication of the inferior vena cava is not an altogether rare condition. In recent years Givens[1] has described two cases observed in the dissecting room of Cornell University Medical College, Ithaca. He also reviewed the literature of some fourteen cases.

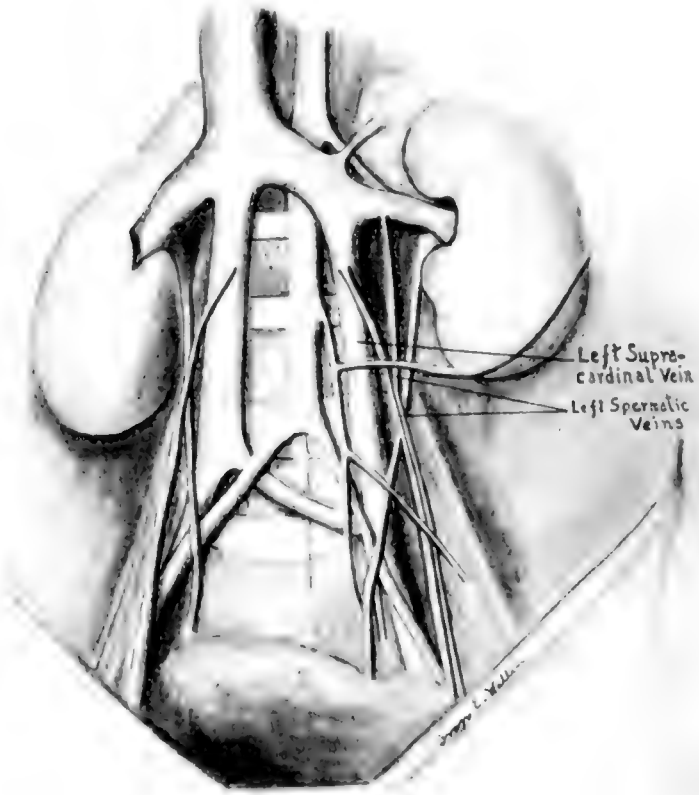
The venous variant here recorded was found in a male cadaver in the dissecting room at the University of Colorado School of Medicine. There were no records of the age or the cause of death. The approximate age was sixty-five years.

Figure 1 illustrates the lower part of the caval system in this subject. In character it is quite similar to the veins found in subject no. 466 described by Givens. The left persistent supracardinal is larger than in Givens' subject. In his specimen the size ratio between the right and left supracardinals was 3 to 1.6. In my subject the ratio is about 2 to 1.5.

An unusual feature in this subject are the two left spermatic veins. So far as I can learn this is the first recorded instance of such a condition. The figure shows the nature of the two veins. The one emptying into the renal vein was about one-third the size of the one emptying into the left supracardinal. The two veins were dissected out for some distance in the cord. With the exception of their proximal parts where they separate to empty into the above-named veins they lie close together in all of their course.

[1] Givens, M. H., 1912. Duplication of the inferior vena cava in man. Anat. Record, 6: 475–486.

The condition found by Huntington and McClure[2] in a human subject may help to explain the duplication of the left spermatic vein. They found fenestrae in the renal collar which established connections between the right spermatic vein and the right renal vein. By a further extension of the fenestrae along the vein a condition might be produced which would be like the character of the veins in this subject.



[2] Personal communication from Professor McClure.

THE ANATOMICAL RECORD, VOL. 20, NO. 2,
JANUARY, 1921

Chinese writing, however, really dates from the time of the 'Yellow Emperor,' Huang-ti (3), 2697 B.C., who ordered his servant Tsang Chih (4) to make words in the form of imitative symbols. These were done in lacquer upon strips of bamboo or palm leaves. Paper and pens came much later. It is said that the vertical arrangement of characters was adopted because it is much easier to write up and down a bamboo than around it. Many characters were elaborated during this period. We are told that Shen-Nung saw a good crop and made a character representing crop ears; that Huang-ti wrote a 'cloud;' Yao (5) a 'turtle;' Yü (6) the 'bell and the kettle,' and so on. The symbols devised represented pieces of string of different lengths with knots at various places in their course. Those consisting of a single knot with a small piece of string attached have suggested the name of 'tadpole characters' for this writing. These characters soon became profoundly modified.

Figures 1 and 2 illustrate the pictorial type of the writing of the Hsia dynasty, 2205 B.C.

A considerable change was also made about the beginning of the Chin dynasty (7), 255 B.C., when Li Si (8) greatly improved the terms and divided them into Ta Chuan (9) and Hsiao Chuan (10). Hsiao Chuan was changed to Chin Chuan (11) during this period. A little later Cheng Miao (12) devised a script called Li Shu (13), or plain square writing, which the first Chin emperor observed and ordered to be used throughout his empire. Paper was first manufactured at this time by Wang Lun (14).

In the Han dynasty (15), 206 B.C., writing was further improved by Chia Fang (16), San Tsang (17), Tsai I (18), and Shih Ching (19), who wrote the word, Han Li (20), as may be seen by reference to figure 3. In the Chin (21) dynasty, 265 A.D., Chung Yin (22) and Wong Hsi Chih (23) changed the writing into a style more nearly approaching that of the present day. Typical Chi-dynasty (479 A.D.) writing is well illustrated in figure 4, and this may be compared with the modern Chinese on pages 125–127.

The works of Huang-ti (3), written over four thousand years ago, 2697 B.C., are the most interesting and original of the great

Chinese medical classics. They stand at the basis of native Chinese medicine. They were written on bamboo strips in words of the tadpole style as a record of questions which Huang-ti asked his servant Chi Pe (24). Later, in the Han dynasty (206 B.C.), they were gathered together into book form and were called *Neiching* (25) *Internal Classics*, *Su Wen* (26), *Inquiries* and *Ling Shu Ching* (27), *The Classics of the Living Spirit*. Unfortunately, they were composed in such genuine literary style that they were difficult to understand until the time of Tang (28), in 620 A.D., when Wang Ping (29) wrote explanatory notes for each book.

In the Chow dynasty (30), 1122 B.C., there lived an anatomist called Chin Yueh Jen (31), who wrote a treatise about the viscera and arteries and called it *Nanching* (32), or *Hard Classics*. This volume contains, among other things, a number of interesting measurements of the weights of the different organs of the men of that time.

In the Han dynasty, 206 B.C., Chang Chi (33) wrote two books (34 and 35) on *The Essentials of the Gold Medicine Case* and on *Fevers*, which are very popular to this day. *The Prescription for Emergency* (36), by Ke Hung (37), appeared in the Chin period (38), 265 A.D. and, about two hundred years later, we meet with Chu Cheng's (39) copy of the *Testament* (40).

Many other authors follow, of whom we may mention Tsao Yuen Fang (41) in the Suei dynasty (42), 689 A.D.; Sun Si Miao (43) and Wang Show (44), in the Tang dynasty (45), 620 A.D.; and Wang Kun, Shen Kue, Chen Chi, Tang Chi, Liu Wen, Han Ti, Pang An Shih, Cheng Ho Chung, Tang Shen, Wang Chu, Hsu Su, Chen Ssu Wen, Hsia Te, Chang Kuo, Chen Tze Ming, Chen Yen, Li Hsun, Yen Yung Ho, and Yang Chih Ying (46–64) —all in Sung dynasty (65), 960 A.D.

Liu Wen Su, Chang Yuan Su, Chang Chung Cheng, and Li Hao (66–69) were prominent medical writers in the Chin (70) dynasty (1200 A.D.), and Wang Hao Ku, Sha-Tu-Ma-Su, Wei Ye Lin, Chu Chen Ting, Wang Kue Juei, Chi Te Chi, Tai Chi Tsung, and Wang Lü (71–78) in the Yuan dynasty (79), 1280 A.D.

The name of Chang Chi Ping (80) is famed as a great anatomist in the Ming dynasty (81), 1368 A.D. Chang wrote a number of books. His most famous one he called *Leiching* (82). It dealt intensively with the visceral and vascular systems.

Important advances were made in the Ching dynasty (83), 1644 A.D., when the Emperor Chien Lung (84) edited an *Encyclopedia of Chinese Medicine* (85) and the government encouraged research. Sheng Teng's (86) book on osteology (87) is replete with interesting observations. In the days of Chia Ching (88), 1796 A.D., a terrible epidemic raged among the children in the town of Chang Li Hsien (89) and many died. A certain magistrate, named Wang Chui Jen (90), visited the public cemetery and found that, since the children were buried in very shallow graves, the hungry dogs were able to uncover the bodies and devour them. Wang's curiosity was so stimulated that he went daily to the cemetery and observed over thirty complete bodies dismembered by the dogs. He was thus enabled to test out the old theories and to make important new observations which formed the basis for his book which he called *A Correction of Faults in Medicine* (91).

At present anatomy is out of date in native Chinese medicine because the doctors only prescribe herbs for the patients and make no attempt at surgical operations.

As it is impossible for me to attempt to review, in the space at my disposal, the whole of the ancient science of anatomy, I shall confine myself to a discussion of splanchnology, angiology, and anthropology.

HISTORY OF CHINESE SPLANCHNOLOGY

Splanchnology and angiology may be traced back to the time of Huang-ti, 2697 B.C. The two subjects were then more or less philosophically treated, and the theories advanced at that time have been handed down to us almost without change and constitute the foundation of native Chinese medicine to-day.

Life is said to depend upon the action of a female principle which embraces a male principle. These principles are opposite powers of vigor or strength which are equal in weight. When

they are properly balanced there will be no disease of any kind and the person will be productive and healthy. These principles are distributed quite differently in the body. The exterior is male and the interior female; the back male and the abdomen female; the viscera male and the parenchymatous organs are female. Each principle has three degrees in quality, namely, great female principle, female principle proper, and young female principle; great male principle, male principle proper, and young male principle (92–97). These three degrees of principle are evenly distributed in their respective organs and viscera.

There are twelve tracts for the transmission of these principles in the general circulation. Translating literally we read that: The hand receives the great female principle of the lung; the foot receives the great female principle of the spleen; the hand receives the female principle proper of the pericardium; the foot receives the female principle proper of the liver; the hand receives the young female principle of the heart; the foot receives the young female principle of the kidney. The hand receives the great male principle of the large intestine; the foot receives the great male principle of the bladder; the hand receives the male principle proper of the small intestine; the foot receives the male principle proper of the stomach; the hand receives the young male principle of the three burning spaces; the foot receives the young male principle of the gall-bladder.

The three burning spaces referred to are situated in the thorax, abdomen, and pelvis and are illustrated in figure 13. They are supposed to be filled with fatty tissue.

We read further, that, since the exterior is male and the interior female, then the male and female principles are as the coat and the lining (98). (Literally, great male and young female are the coat and the lining; male proper and young female are the coat and the lining; young male and great female are the coat and the lining.)

The quality of the principles varies in different organs and we have corresponding differences in the amount of air and of blood. The great male principle usually has much blood and very little air; the male principle proper has both blood and air

in good quantity; and the young male principle has very little blood but much air. The great female principle has much air and little blood; the female principle proper has much blood but little air; and the young female principle has very little blood but much air.

The liver (fig. 7), heart (fig. 5), spleen (fig. 8), lungs (fig. 9), and kidneys (fig. 16) are commonly called the five parenchymatous organs, while the gall-bladder (fig. 15), stomach (fig. 14), large intestine (fig. 16), small intestine (fig. 11), bladder (fig. 12), and the three burning spaces (fig. 13) are regarded as the six viscera. The pericardium (fig. 6) and brain may also be referred to as organs. There are some differences of opinion about this, however, because Chi Pe, the servant of Huangti, 2697 B.C., claimed that the brain, bone-marrow, gall-bladder, and uterus are premanent singular bodies, which would indicate that the brain and bone-marrow may also be classified as true organs. The meaning of the term organ (99) is to store up, but not to eliminate, while the word viscera (100) means to eliminate, but not to store up.

Huangti, 2697 B.C., describes in his book on *Neiching*, or *Internal Organs*, what the different organs store. We read that the liver (fig. 7) stores the blood, which contains the soul; that the heart (fig. 5) stores the pulse, which contains the spirit; that the spleen (fig. 8) stores the nutrition, which contains the thoughts; that the lungs (fig. 9) store the breath, which contains the energy, and, finally, that the kidneys (fig. 16) store the germinating principle, which contains the will. He explains also his idea of their action. The liver has a rancid odor, a sour taste, a brown color, makes the sound *chüeh* (101), a note in Chinese music, and at will is the seat of anger. The heart has an odor of toast, a bitter taste, a brownish-red color, makes the sound *chih* (102), and at will is the seat of happiness. The spleen has a fragrant odor, a sweet taste, a yellow color, makes the sound *kung* (103), and at will is the seat of thought. The lung has a fishy smell, a hot taste, a white color, makes the sound *sheng* (104), and is the seat of sorrow. The kidneys (fig. 16) have a putrid smell, a salty taste, a black color, make the sound *yu* (105), and at will are the seat of fright.

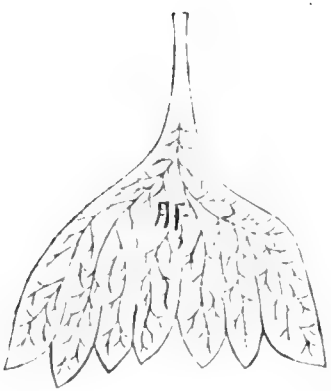
6



7

8

Fig. 5 Heart with three cords, as kidney, liver, and spleen (Huang-ti period, 2697 B.C.).
Fig. 6 Pericardium.
Fig. 7 Liver.
Fig. 8 Spleen.

These five organs are supposed to work harmoniously together and serve in the development of the body as follows: The liver produces the ligaments, forms the heart, and controls the lungs. The heart produces the blood, forms the spleen, and controls the kidneys. The spleen produces the flesh, forms the lungs, and controls the liver. The lungs produce the skin and hair, form the kidneys, and control the heart. The kidneys produce the bone-marrow, form the liver, and control the spleen.

The five organs control the five senses and all parts of the body. The liver has an eye at its opening, converts the fluid into tears, supplies the ligaments, and nourishes the nails. The heart has the tongue at its opening, converts the fluid into perspiration, supplies the pulse, and nourishes the complexion. The spleen has the mouth at its opening, converts the fluid into saliva, supplies the flesh, and nourishes the lips. The lungs have the nose at their opening, convert the fluid into snivel, supply the skin, and nourish the fine hairs. The kidneys have the ears as their openings and also the genito-urinary region, they convert the fluid into spittle, supply the bone, and nourish the hairs.

The five organs are related to the six viscera which answer each other in their action (p. 103). The lungs relate to the large intestine, which answers the skin; the heart relates to the small intestine, which answers the arteries; the liver relates to the gall-bladder, which answers the ligaments; the spleen relates to the stomach, which answers the muscle, and, lastly, the kidneys relate to the three burning spaces and the bladder, which answer the skin and the hairs.

The functions of the organs and viscera are described as follows: The heart is the king who directs the body, the lungs are the promulgators who carry out his orders. The liver is the general whose duty it is to meditate carefully. The gall-bladder is the central legal officer, who makes judgments. The pericardium is the minister to bring happiness. The spleen is the officer of granaries who creates the five tastes. The large intestine is the officer of communications who starts all sorts of changes. The small intestine is the receiving office in which digestion is carried on. The kidney is the officer of vigor or strength who

Fig. 12 Bladder and urethra.

serves through his intellect. The three burning spaces constitute the sewage system from which all the canals drain into the bladder where the fluid is stored; after having been acted upon by the air, it is finally passed out.

The surrounding walls of the organs and viscera are also described: The thorax and abdomen constitute the city wall and the pericardium (fig. 6) is the palace of the king; the stomach is the granary and the throat and small intestine the post-office. The five openings of the stomach are called the doors, entrances and outlets (of the granary). Water and grain enter the body by the esophagus and air by the trachea. The food enters the stomach where essence soaks into it and it becomes air, which, if of nourishing nature, passes into the lower burning space. The air, entering at the trachea, passes through the epiglottis, which is the door of the voice. The mouth and lips are the fan for the voice, the tongue the machine for the voice, and the uvula the pass for the voice. The larynx divides the air. The breath, coming from the lungs, is thought to act upon the transverse bone (hyoid) and the tongue (in speaking).

In the same book Huangti gives some measurements of the alimentary tract which will be of interest to anthropologists (see also p. 121).[2]

Distance from lip to teeth	$\frac{1}{2}$ inch
Width of mouth	$2\frac{1}{2}$ inches
Distance from teeth to epiglottis	$3\frac{1}{2}$ inches
Capacity of mouth and pharynx	5 Ko (166)
Weight of tongue	10 oz.
Length of tongue	7 inches
Width of tongue	$2\frac{1}{2}$ inches
Weight of esophagus	10 oz.
Width of esophagus	$1\frac{1}{2}$ inches
Length of esophagus	1 ft. 6 inches
Length of stomach stretched out	2 ft. 6 inches
Circumference of stomach	1 ft. 5 inches
Diameter of stomach	5 inches
Capacity of stomach (dry measurement)	3 tou (107) 5 sheng (108)

[2] Unfortunately, we cannot ascertain their equivalents in present-day standards.

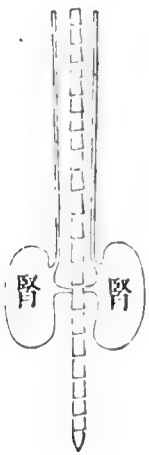
15



16

Fig. 13 The three burning spaces (2697 B.C.).
Fig. 14 Stomach.
Fig. 15 Gall-bladder.
Fig. 16 Kidney.

Circumference of small intestine	2½ inches
Diameter of small intestine	$\frac{5}{16}$ inch
Length of small intestine	33 ft.
Capacity of small intestine (dry measurement)	2 tou, 5 sheng
Circumference of large intestine	4 inches
Diameter of large intestine	1½ inches
Length of large intestine	20 ft.
Capacity of large intestine (dry measurement)	1 tou
Circumference of rectum	8 inches
Diameter of rectum	2½ inches
Length of rectum	2 ft. 8 inches
Capacity of rectum	2½ Ko

The small intestine is attached to the spine posteriorily, and anteriorily to the navel. It exhibits sixteen loops. The large intestine lies on the left side of the navel and has also sixteen curves.

In the book called *Nanching*, or *Hard Classics*, written by Chin Yüeh Jen in the Chow dynasty, 1122 B.C., we find the morphology and weights of the different organs and viscera described. It differs from *Neiching* in the following particulars:

Liver, three left lobes and three right lobes	4 catties, 4 oz.
Heart, seven holes and three pillars contains 3 Ko of vigorous principle	12 oz.
Spleen, flat, 3 inches thick, 5 inches long, contains ½ catty of loosening extract	3 catties, 3 oz.
Length, eight lobes	3 catties, 3 oz.
Kidneys, two in number	1 catty, 1 oz.
Gall-bladder rests on the short lobe of the liver, contains 3 Ko of essential fluid	3 oz. 3 drams
Stomach	2 catties, 2 oz.
Small intestine	2 catties, 14 oz.
Large intestine	2 catties, 12 oz.
Bladder when stretched 9 inches long, contains 9 sheng, 9 Ko of urine	9 oz. 2 drams
Trachea, 2 inches wide, 1 ft. 2 inches long, in 9 sections	12 oz.
Rectum	12 oz.

In the Tang dynasty, 620 A.D., Sun Ssu Miao wrote two books in which he followed the descriptions given in the *Nanching* over 1700 years earlier with but slight modifications. However, the weights of the intestine and stomach and the length of the intestine differ somewhat from those given by Huangti in his

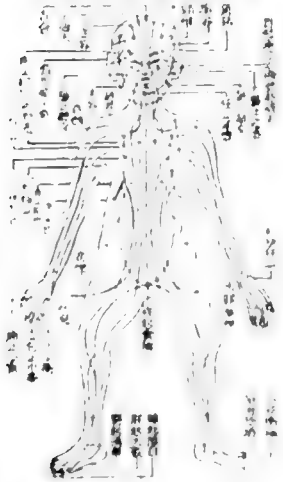
Neiching, 2697 B.C. Sun Ssu Miao described two bladders, one receiving the 'essential fluid,' and the other, fluid and urine. In his books each organ or viscus had attached to it the name of a protecting god. This indication of theocratism is not, however, found in later writings on Chinese medicine. Controversy has been active regarding the three burning spaces (fig. 13) for upward of four thousand years. In the *Nanching* we read that the three burning spaces have no form, that they control the air (vigor), and that the two kidneys should be classed as two separate and distinct organs, the left being the real one and the right the 'gate of life.' The 'gate of life' is said, in the male, to contain the semen and, in the female, the uterus. This conception is entirely different from that advanced in the *Neiching*. Huangti, 2697 B.C., Wang Shu Ho (109), Huei Tsung (110) and Sun I Kuei (111), all contend that the burning spaces exist only in name, but not in form (108 and 109).

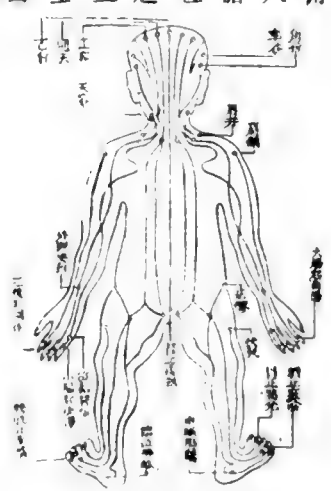
The second theory assumes that the burning spaces exhibit definite structure. This view is actively supported by Hsü Tun (112) and Chen Wu Tse (113) in the Sung dynasty. The former observed a piece of fatty membrane, about the size of a man's hand, near the bladder and two whitish cords emerging from it and running to the brain. He concluded that the membrane constituted the burning spaces (114). In the Ming dynasty, 1368 A.D., Yü Po (115) writes that the fatty membrane in the thorax also belongs to the three burning spaces. Chang Chi Pin holds the view that the thorax and abdomen are constructed like a large sac (116), that the inner lining is very red and that these linings are in truth the burning spaces. He debates the subject at length.

According to a third theory, the three burning spaces are capable of subdivision into upper and lower parts governing corresponding regions of the body. This idea is due to Li Kao (117) writing in the Yuan dynasty, 1280 A.D. (118-119). Later in the Ming dynasty, Ma Shih (120) described the three burning spaces as being a compound of two sets, one without form and the other with form. He says in his book (121) that the upper, middle, and lower burning spaces, described in *Nanching*, are

21



22



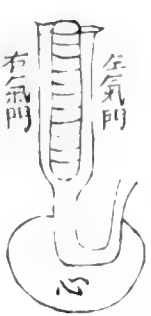
23

Fig. 21 Body measurements, back view (2697 B.C.).
Fig. 22 Traveling vessels with their needling points, front view.
Fig. 23 Ditto, back view.

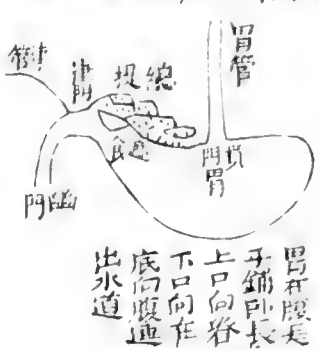
without form and filled with air, while the three burning spaces of the hand, foot, and young male have form.

A few words may here be said about the term 'Mingmen,' or 'gate of life' (122), which is first used in the *Nanching*, 1122 B.C. The still older book I-Ching (123), originally written by Fuhsi (124) in 2852 B.C. and revised by Wen Wang (125) in 1122 B.C., says that "Keep in the learning of water, to which the kidney belongs, and you will be strong" (126). Hoa-show (127) claims, in the Yuan period, 1280 A.D., that the air of the 'gate of life' connects with the kidney. We find that later, in the Ming period (1368 A.D.), Chao Hsia Ke (128) advanced evidence that the 'gate of life' is located at the needling point in the lumbar region, and further that female water belongs to the right kidney and male water to the left, between which there is a space of $1\frac{1}{2}$ inches. This area he believed to be the 'palace of life' from which the true fire, which is without form, is sent (129). But Sun I Kuei (130) expressed a different view, according to which the 'gate of life' is the original or mobile air of the body which plays between the two kidneys (131). Chang Chi Pin is a little more specific in his theory that the 'gate of life' corresponds to the orifice of the uterus where the kidney stores its essence. In Taoism this location is called 'Tautien' (132). According to still another view, the 'gate of life' is at the back opposite to and at the same level as the navel (133). All these conceptions indicate that the men of the time were trying to reverse the error of the *Nanching* which described the 'gate of life' as resident in the right kidney.

Between the Sung and Yuan dynasties, 960-1280 A.D., there is but little improvement in the science of splanchnology. The publication of Chao Hsien Ke's (134) *Morphological Atlas* (135) and of Sun I Keui's book on *Human Internal Organs* (136), mark, however, a certain advance. Subsequently, in the Ching period, 1644 A.D., Feng Chiao Chang (137) reversed the teachings of Chao and improved his descriptions. In Feng's book we read that the lung is attached to the third vertebra and hangs down in four lobes which are gray in color, that it possesses twenty-four lobes in order to provide for the circulation of air



24



25

Fig. 27 Liver with gall-bladder.

from the various organs, that it is empty as a beehive with no opening below, and that it fills on inhalation and empties on exhalation. The spleen is attached at its upper left end a little below the eleventh vertebra, it is sickle-shaped, and is enveloped by the same membrane as the stomach, and moves when a voice is heard, grinding on the stomach, and aiding in transportation and digestion. The pericardium is situated above the transverse membrane (diaphragm), with which it is connected, and below the vertical membrane, it has yellow fat and encloses the heart, to which it is connected by a thin fibrous membrane-like silk. The heart is attached to the fifth vertebra lying below the tube of the lung and above the diaphragm; it is conical in shape like a lotus bud, with openings at the side, but none below; it shows some individual variation, being connected with the tongue above and by means of four cords with the lung, spleen, liver, and kidneys. The diaphragm is attached to the ribs and to the spine and prevents the impure air from coming up from below. The bladder lies at the level of the nineteenth vertebra below the kidneys and in front of the large intestine; it possesses an opening below, but none above. Feng remarks that according to some books the bladder has an upper opening only and that others say that it has no opening at all, opinions which he considers to be quite erroneous. He believes that the urine is produced through a process of air change in the body. The kidneys are two in number, each the shape of a bean, one on either side of the spine, and separated by about $1\frac{1}{2}$ inches. They are enveloped in yellow fat and each is supplied with two cords which run up and down. The upper pair are attached to the heart and the lower pair run down along the spine, pass over the coccyx, where they enter a space about half the size of a man's hand; they leave this space through two holes and pass upward along with the spinal cord to the brain (138).

In the Ching dynasty (1644 A.D.), during the days of Chia Ching and Tao Kung (1796–1821 A.D.), there lived a Chihli medical man, Wang Ching Jen, who spent forty years in the study of splanchnology and wrote a book entitled *Corrections of Faults in Medicine* in order to overthrow the teaching in the

Fig. 31 Vena cava and aorta.

Nanching. Wang made use of his exceptionally good opportunities for study. His book is based upon twenty-four corrected pictures of the organs and viscera, of which figures 25 to 31 will serve as examples, and contains the following five essays:

1. *The Epiglottis, Right and Left Air Gates: the Main Protective Tube, the Main Nourishing Tube; and Air and Blood Centers.*
2. *The Route of Digestion and the Excretory System.*
3. *The Brain.*
4. *The Air, the Blood, and the Pulse.*
5. *The Absence of Blood in the Heart.*

We may mention in conclusion Peng Tsung Hai (139), from the province of Ssuchuan, who wrote during the Kwang Hsu period, 1875 A.D. He was a follower of Wang and was fortunate in being able to secure an atlas of western medicine for comparison in testing out the theories in *Neiching*. Nevertheless, he holds to the old views and describes the 'gate of life' as corresponding to the cords of the kidney and the fat lying below the cords as the lower burning spaces. The fat in the region of the omentum corresponds in his mind to the middle burning space and that above the diaphragm to the upper burning space. He describes that part of the bladder which connects with the fat as the place where the water enters. And finally he seems convinced that the brain carries out the action of the heart, which is in direct opposition to the theories of Chin Cheng Hsi (140) and Li Chih Chen (141), the former being of the opinion that the brain is the seat of memory and the latter that it is the 'palace of God' (142, 143).

HISTORY OF CHINESE ANGIOLOGY

Angiology and osteology are the only sciences in which the arts of acupuncture, cautery, and osteopathy are used therapeutically. During the time of Huangti, 2697 B.C., acupuncture was used extensively as a method for the treatment of disease (*Neiching*, vol. 14), but just how the practice originated we cannot tell. We have read about the relations of the five organs to the different parts of the body, how the skin relates to the

lung, muscle to spleen, vessel to heart, ligament to liver, and bone to kidney; now, when the needle punctures the different tissues at various depths, there will be a reaction on the organ to which the tissue is related.

The vascular system makes connections between the organs and viscera which are placed inside the body and all the other parts.

The traveling vessels circulate the blood and the air to nourish the male and female principles, to moisten the bones and ligaments, and to lubricate the joints. Twelve pairs are recognized with their respective branches (figs. 22 to 23).

1. The hand great female lung vessels from the middle burning space to the tip of the thumb.

2. The hand male proper large intestine vessels from the tip of the thumb and of the small finger to the large intestine.

3. The foot male proper stomach vessels from the middle of the nose to the middle toe of the foot.

4. The foot great female spleen vessels from the great toe to the lower part of the tongue.

5. The hand young female heart vessels from the heart to the inside of the little finger.

6. The hand great male small intestine vessels from the little finger to the small intestine.

7. The foot great male bladder vessels from the inner corner of the eye to the little toe of the foot.

8. The foot young female kidney vessels from the little toe to the root of the tongue.

9. The hand female proper pericardium vessels from the middle of the stomach to the tip of the middle finger.

10. The hand young male three burning space vessels from the tip of the little finger to the three burning spaces.

11. The foot young male bladder-vessels from the outer angles of the eyes to the little toes.

12. The foot female proper vessels from the hairy spots on the big toes to the vertex of the head connecting with the central vessels (144).

There are also eight singular traveling vessels as follows:

1. The Chung Moa (145), or 'ventral rising vessel.'
2. The Jen Moa (146), or 'responsible vessel.'
3. The Tu Moa (147), or 'governor vessel.'
4. The Tai Moa (148), or 'girdle vessel.'
5. The Yin Chiao Moa (149), or 'outer heel vessel.'
6. The Yang Chiao Moa (150), or 'inner heel vessel.'
7. The Yang Wei Moa (151), or 'external longus vessel.'
8. The Yin Wei Moa (152), or 'internal longus vessel.'

Though the twelve pairs of traveling vessels are separated in their course, six regular anatomoses occurring in the extremities are recognized:

1. The foot great male with foot young female.
2. The foot young male with foot female proper.
3. The foot male proper with foot great female.
4. The hand great male with hand young female.
5. The hand young male with the heart.
6. The hand male proper with the hand great female.

The traveling vessels are usually deeply placed and concealed in the muscles, but one pair, as it passes the external malleolus, lies superficially and can easily be seen to pulsate. Each vessel has definite places in its course where the pulse air may be let out. Some of them have more than others, but the total number is 365. These places are called the 365 needling or puncture points (153).

In addition to the twelve pairs of traveling vessels, we have twelve pairs of traveling ligaments, following the same course, to deal with. The ligaments are more closely associated with the limbs, muscles, and joints (154). The pulsating vessels are not able to pass over the larger joints, where they turn to the skin and make their connections so that we are unable to trace their pulsations. They are fifteen in number (155).

The stomach has a large vessel for itself. The branches of the vessels are called *Sun* (156), or descendents. They serve for the overflow of the strange and malicious excess and for the conveyance of nourishment and protection. The large junctions of the vessels with the muscles are called *Hui* (157) and the smaller ones *Hsi* (158). In the muscular fibers and the muscular

junctions there are routes for nourishment and protection, where the air meets. To correspond with the needling points 365 small branches of vessels and 365 muscular junctions are recognized (159). Each of the five organs has five traveling vessels, making in all twenty-five small traveling vessel spots; and each of the six viscera six traveling vessels, making thirty-six more small traveling vessel spots.

Counting the twelve traveling vessels and the fifteen pulsating vessels, we have altogether twenty-seven air routes which go up and down. The site where each starts is called the spring, the current carries nutrition which flows toward the termination or needling spot.

There are likewise 365 articulations which receive air in the following manner. The five organs have six viscera, and the six viscera twelve springs whence the air circulates through the four passes (at shoulders and hips) and is distributed directly to the joints.

With reference to the pulse, we read that in the normal condition there is one beat for each expiration and inspiration. When each expiration has three beats and each inspiration four it is said to be the pulse of death (160).

When we remember that this complicated system which we have outlined has been handed down to us from Huangti, over four thousand years ago, we cannot help admiring the thoroughness and ingenuity which has been displayed. The obvious inconsistencies and contradictions are surely to be expected.

In the Tang period, 620 A.D., Sun Ssu Miao collected the atlases used by prominent doctors and wrote an interesting book on *Acupuncture and Cautery*. He made illustrations in five colors showing 650 needling points in three planes (front, back, and side views). He listed 345 special names for the different points (161). Unfortunately, the original pictures in his atlas have been lost. A few years later Wang Tao (162) revised the atlas and made twelve pictures corresponding to those in the books of Huangti, Sun, and others (163). We still have the descriptions, but these illustrations have also been lost.

In the Sung dynasty (960 A.D.) the Emperor Jen Tsung (164) ordered Wang Wei I (165) to construct a bronze figure in which all the old theories of anatomy were to be corrected and incorporated. Holes were drilled to represent the needling points, in accordance with the descriptions of Sun Ssu Miao (166). The interior of the figure is fitted with models of organs and viscera surrounded with water.

During this dynasty two important works were written by Hsi Fang Tzu (167) entitled *Needling Cautery Classics on the Bronze Figure* (168) and *Ming Tang Needling Cautery Classics* (169). About half the needling points mentioned differ from Sun's descriptions. Several other papers of less importance dealing with acupuncture and cauterization appeared at this time, which it will be hardly worth while to consider here.

Yang Chi Chow (170) collected all the old records and compiled a system of acupuncture and cauterization (171) in the Ming dynasty, 1468 A.D., which deserves mention before concluding this section.

ANTHROPOLOGY

The measurements which I have already given (pp. 107, 109) will indicate clearly the intense interest which the old Chinese anatomists took in determining physical standards. Huangti, many years ago, made a conscientious attempt to ascertain and record the average measurements of the men of his day. He said to his servant Po-Kao (172): "I desire to know the average length of the bones if a person has a height of seven feet and a half." Unhappily, the standard has been lost, so that we cannot ascertain the absolute value of the feet and inches used as units by Huangti, but the figures still possess a certain relative value. In answering, Po-Kao gave the following measurements (figs. 20 and 21):

Head circumference	2 ft. 6 inches
Thorax	1 ft. 5 inches
Hairy area of scalp	1 ft. 2 inches
Vertex of head to angle of mandible	1 ft. 0 inch
Thyroid eminence to interclavicular notch	2 inches

Sternum length	9 inches
Sternum to umbilicus	8 inches
Umbilicus to transverse bone (pubes)	6 inches
Width of transverse bone	6½ inches
Upper border of the pubes to upper border of internal condyle	1 ft. 8 inches
Upper border of internal condyle to its lower border	3½ inches
Lower border of internal condyle to internal malleolus	1 ft. 3 inches
Internal malleolus to sole	3 inches
Back of knee-joint to foot, dorsal surface	1 ft. 6 inches
From dorsal surface of foot to ground	3 inches
External angle of frontal bone to the clavicle	1 ft.
Clavicle to axillary space	4 inches
Axillary space to twelfth rib	1 ft. 2 inches
Twelfth rib to hip-joint	6 inches
Hip to the middle of the knee	1 ft. 9 inches
Knee to external malleolus	1 ft. 6 inches
External malleolus to calcaneus	3 inches
Calcaneus to ground	1 inch
Between two mastoids	9 inches
Between two ears	1 ft. 3 inches
Between two malar prominences	7 inches
Between two hips	6½ inches
Foot length	1 ft. 2 inches
Foot width	4½ inches
Shoulder to elbow	1 ft. 7 inches
Elbow to wrist	1 ft. 2½ inches
Wrist to first joint of middle finger	4 inches
First joint of middle finger to tip of finger	½ inch
Border of hair of scalp to seventh vertebra	2½ inches
Seventh vertebra to sacrum	3 ft.

In the Sung period, 960 A.D., the emperor ordered his physicians to edit a system of medicine (173), in which we can find some further measurements, but unhappily the method of making them has not been described. We read that there are 365 bones in the male and five less in the female, that 190 of them are concealed so that they cannot be seen and that 256 possess bone-marrow.

The works of Huangti remain perhaps the most complete on record. He is certainly to be regarded as the father of Chinese medicine.

CONCLUSIONS

It is quite evident from the foregoing account that in the beginning the science of anatomy in China was based upon actual dissection of the human body.

The most notable evidence in favor of this conclusion is briefly as follows: Chipo, the servant of Huangti, 2697 B.C., writes that "after death the body may be dissected and actual observations made." A little later we read that Yin Chow (174), 1122 B.C., killed Pi Kan (175) and dissected his heart to discover whether it had seven openings. In the Han period, 206 B.C., Wang Mang (176) slew Chen Hsun (177) and dissected his arm; the same gentleman also captured a revolutionary and ordered his physicians to dissect him.

We find, also, that executions were frequently adapted to anatomical purposes. For instance, Liang Shao Pao (178), 960 A.D., sent his medical officer with an artist to make pictures during an execution of thieves, probably by the rather slow slicing process; and the local officer, Li I Hang (179), employed doctors and artists and labored himself to make dissections and to correct drawings during an execution at Ssu Chow. Yang Chik (180) compared these drawings with the old books, found them to be correct, and accordingly constructed his famous *Atlas of Truth*.

We have already mentioned the terrible epidemic which raged among the children in the town of Chang Li Hsieh in the days of Chia Ching (1796 A.D.), and of how a certain magistrate, named Wang Chin Jen, happened to visit the public cemetery where he found that hungry dogs were uncovering the bodies, hastily buried in shallow graves, and devouring them. Wang's curiosity was so aroused that he went daily to the cemetery and observed over thirty complete bodies dismembered. He was thus enabled to test out the old theories and to make important new observations which formed the basis for his book called *A Correction of Faults in Medicine*.

Unfortunately, this direct method was soon replaced by a rule of authority somewhat similar to that which reigned in Europe

before the Renaissance. For instance, *The Essentials of a Gold Medicine Case* and a book on *Fevers*, written by Chang Chi in the Han dynasty (206 B.C.), remain very popular to this day. With the reintroduction of direct observation and a true appreciation of the value of experimental methods, we may look for great advances.

Resumen por el autor, Oliver H. Gaebler
Universidad de Missouri.

El epitelio de la vejiga durante la contracción y la distensión.

El presente trabajo trata del problema de sí durante el proceso de distensión fisiológica, el numero de capas celulares del epitelio de la vejiga permanece constante o, por el contrario, si disminuye, es decir, si las células epiteliales simplemente se aplanan o si se disponen en un número menor de capas. En los estudios llevados a cabo, el autor ha empleado material procedente de ratas, conejillos de indias, y conejos, pero el trabajo más importante fué hecho en conejos.

Para resolver el problema se han empleado dos métodos. El primero consiste en contar el número de capas del epitelio en vejigas en diversos grados de distensión, comparando dichas capas con el número encontrado en vejigas contraidas. El segundo método empleado depende del hecho de que sí no hay una disposición de las células epiteliales en un número menor de capas, la relación que representa el aplanamiento del epitelio en cualquier dirección debe ser idéntica a la que representa el aplanamiento de sus células en la misma dirección. Estas relaciones se determinaron mediante medidas del epitelio y de diez mil células, en dos series de vejigas de conejos.

Las conclusiones obtenidas por ambos métodos son: 1) La distensión fisiológica moderada no disminuye el número de capas de células epiteliales; 2) La distensión fisiológica máxima no disminuye las capas citadas en mas del 12.5 por ciento; 3) Las células de las capas más profundas no están unidas tan íntimamente como las de las capas superficiales, y 4) Las células no sufren una contracción ulterior después que ha comenzado el plegamiento del epitelio.

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED
BY THE BIBLIOGRAPHIC SERVICE, NOVEMBER 15

BLADDER EPITHELIUM IN CONTRACTION AND DISTENTION

OLIVER H. GAEBLER

Anatomical Laboratory, University of Missouri

NINE FIGURES

The main problem with which this paper deals may be stated in the following questions: Does the epithelium of a bladder in distention have the same number of layers of cells as the epithelium of a similar bladder in contraction? Does the process of distention involve only a stretching of the cells, or also an arrangement into fewer layers?

This problem has been discussed for many years. London ('81) studied the relation between thickness of the epithelium and degree of distention of the bladder, because he believed that data obtained would be of interest in connection with the problem of resorption of substances from the urine. Since the epithelium of the bladder forms a barrier between the contained urine and the capillaries in the underlying connective tissue, the thinning out of this epithelium on distention was thought to be significant in connection with the stated problem. In regard to the number of layers of cells, London ('81) said that there was an apparent diminution during distention, but an actual diminution only in the number of layers of nuclei, and not in the number of layers of cells.

Dogiel ('90) studied the histology of bladder epithelia of mice, rats, and various other mammals, and claimed that the cells of the first two layers, counting from the surface layer, were so interlocked by protoplasmic processes that there was no possibility of a change in their relative position occurring during distention.

Eggeling ('01–'02) and many others published articles on the histology of bladder epithelium, but did not touch upon the

problem under discussion in this paper. Harvey ('09) described the variations in all the layers of the walls of both bladder and ureter during contraction and distention. In regard to the bladder epithelium, he says that there is a decrease of 50 per cent in the number of layers of nuclei during distention, and also a decrease in the actual number of layers of cells.

Concerning the human bladder, one histologist (Lewis and Stöhr, '13, p. 324) says the following: "The epithelium has been described as two-layered in the distended bladder, the outer cells having terminal bars; in the contracted condition it becomes several layered, and the bars form a net extending into the epithelium. Thus it is not believed that during distention the layers merely flatten; they are thought to 'slip by each other.' The columnar cells may, however, become extremely flat."

The various observers, using material from many sources, and employing numerous methods, have, therefore, reached several conclusions that bear upon the particular problem here discussed. Some of them have pointed out the decrease in the number of layers of nuclei in bladder epithelium during distention and have determined this decrease quantitatively. Some have stated that while there is a decrease in the number of layers of nuclei, there is no decrease in the actual number of layers of cells. Others have claimed that there is an actual decrease in the number of layers of cells during distention, but have made no statements regarding the extent of this decrease. The following studies were therefore made for the purpose of finding out whether there is any diminution in the number of layers of cells during distention, and, if so, how great the diminution is.

MATERIALS AND METHODS

In the experiments that follow the animals used were white rats, guinea-pigs, and rabbits. The preliminary work, done on some material from each of these three sources, suggested that the results would be very much alike, if not identical, for the three animals, and since rabbit material seemed the most favorable for the particular methods of procedure and staining required, the final work was done on rabbit material.

In obtaining bladders in various degrees of contraction and distention, it is evident that the more nearly normal, or physiological, the process of contraction or distention, the less open to objection is the result. Bladders in various degrees of normal distention or contraction can be obtained by simply taking animals from their cages, killing them at once, and relying on chance. If chance killing does not yield a sufficient number of contracted bladders, female rabbit bladders can be made to contract by pressure on the lower abdomen or by irritation of the urethra. With male rabbits the pressure method is less reliable. If completely contracted bladders are wanting, they can be produced by cutting the urethra or opening the bladder in any way, in an animal that has just been killed. If greatly distended bladders are desired, the animals are given an abundance of water, taken from their cages and played with or excited in any way for thirty minutes to an hour, and suddenly killed.

To fix a bladder found in partial or complete distention, the urethra and ureters are clamped with one hemostat immediately after the abdomen has been opened, and are then cut on the side of the hemostat away from the bladder, so that the urine is retained. The bladder is then immersed in saturated mercuric chloride solution for two or three minutes. This destroys the contractility of the muscle cells. In guinea-pigs a longer exposure was needed to accomplish this result. The bladder is next transferred to physiological salt solution, cut open, washed out in several changes of salt solution if necessary, and returned to mercuric chloride solution for twelve hours.

In completely contracted bladders, the part used for sections is a cylindrical piece secured from the middle of the bladder by two parallel cuts, made at right angles to the long axis of the bladder and 2 or 3 mm. apart. In partly or completely distended bladders, a corresponding equatorial zone, about 5 mm. wide, is cut out after fixation. This zone is cut open anywhere, measured just before imbedding, and cut into a convenient number of pieces, all of which are imbedded.

The solution of the problem depends fundamentally upon an unmistakable staining of the cell boundaries. Such staining will

prevent overlooking of cells whose nuclei are not included in the section, and will enable one not only to count the number of layers of cells, but also to measure accurately the size of the cells. A number of staining methods were tried, but it was found that the following iron hematoxylin methods, when used with rabbit material, were the most successful:

First method. 1. Fix in a saturated solution of mercuric chloride in physiological salt solution.

2. Stain with freshly prepared Hansen's hematoxylin to which no sulphuric acid has been added (Lee, '13, p. 159) until the sections are very black. This requires fifteen to thirty minutes. Decolorize in 2.5 per cent iron alum solution, to the point where cell boundaries show plainly, paying no attention to the layers of the bladder wall other than the epithelium. Clear and mount without counterstaining.

Second method. Mallory's chloride of iron hematoxylin method, as described in Mallory and Wright's 'Pathological Technique,' page 310. In differentiating, again watch the epithelium only.

Although the solution of the problem depends fundamentally upon the success of the foregoing procedures, one very important complication remains. Due to the complexity of the folding of the epithelium of completely contracted bladders, sections taken at right angles to the long axis of the bladder will be perpendicular to the epithelium at only a few points, and tangential everywhere else (fig. 9). This difficulty is avoided by securing bladders that have contracted just to the point where folds begin to form, and fixing them in this condition by the method previously described. Sections can then be obtained that run perpendicular to the surface of the epithelium, just as carefully prepared sections of distended bladders do. This simplifies the entire problem a great deal.

Although important results were obtained from rat and guinea-pig material, the results obtained from six rabbits will cover all the facts ascertained, so it will be best to give the details of this part of the work, and pass by the remainder to avoid repetition.

Six rabbits, all of the same litter, all female, and a little less than half grown, were dealt with as follows:

Rabbit no. 1. Weight, 26 oz. The rabbit was well supplied with water, Tuesday, January 6, 1920; taken from cage at 8:30 P.M., played with for half an hour, and killed by a blow at 9 P.M. The abdomen was opened. The bladder was found widely distended, was clamped off, removed, and suspended in bichloride solution for two minutes. Its equator measured 10.4 cm. It was suspended in normal saline while the base was cut off. No contraction followed. The bladder was washed out and replaced in bichloride at 9:10 P.M.

Rabbit no. 2. Weight, 26 oz. This rabbit was taken from the cage, January 6, 1920, 9:15 P.M. Pressure was put upon the lower abdomen at once, and resulted in passage of a small amount of urine. The animal was left for a minute, and was then killed by a blow. The abdomen was opened, and the bladder found completely contracted. The bladder was removed, washed out with physiological salt solution, and put in bichloride at 9:20 P.M.

Rabbit no. 3. Weight 26 oz. This rabbit was killed Saturday, January 24, 1920. The procedure and results were very similar to those for rabbit no. 1, excepting that the distention was smaller. The equator of the bladder measured 8.2 cm.

Rabbit no. 4. Weight, 26 oz. The rabbit was killed Saturday, January 24, 1920. Procedure and results were very similar to those for rabbit no. 2. The bladder was not found completely contracted, but contracted completely when the base was cut.

Rabbit no. 5. Weight, 24 oz. The bladder of this rabbit was partly emptied by pressure on the abdomen. The animal was then killed by a blow, and the bladder was found partly contracted. It was clamped off and removed, suspended in bichloride three minutes, suspended in normal saline while the base was cut off, and was then washed out. The folds in the epithelium had just begun to form in one region of the bladder. The bladder was replaced in the fixative within ten minutes after the death of the animal, January 26, 1920.

Rabbit no. 6. Weight, 24 oz. The rabbit was killed on February 1, 1920. The procedure and results were practically identical with those for rabbit no. 5.

The sections were all cut 10μ thick. While this is thicker than is usually recommended for the methods of staining used, staining of cell boundaries in the epithelium is in no way interfered with, and sections of this thickness were valuable because the relations in any one focal plane could be more firmly established by focusing at various depths.

RESULTS OBTAINED BY COUNTING THE NUMBER OF LAYERS OF EPITHELIAL CELLS

After all these specimens had been sectioned, two methods of approaching the problem were used. The first, and most obvious, was simply to count the number of layers of cells in the epi-

thelia of the various bladders. In the completely contracted bladders, with complexly folded epithelia, the number of layers varies a great deal, due to the great number of places where the section is tangent. But at frequent intervals the number of layers is three to four, and if the number of layers is approximately the same over the entire bladder, these places must be the points where the section is cut perpendicular to the surface of the epithelium, and hence the points giving the correct number of layers. The number of cells in sections from bladders that had contracted just to the point where folds began to form was also counted, and in these there were regularly three to four layers. The number of layers in the distended bladders was also three to four. In all cases the variation was slightly greater than this, for there were points at which only two layers of cells could be distinguished, and others at which there were no less than six layers, but three to four layers constituted the most frequent thickness.

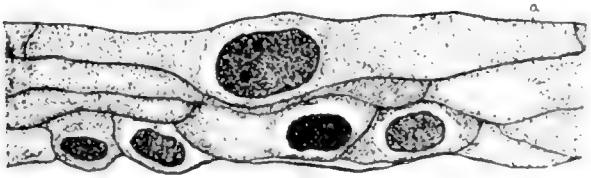
The sections were studied under oil immersion, at a magnification of 950. With this magnification, the cell boundaries stained by the indicated methods stand out with surprising clearness, both in the contracted and in the distended specimens. Low magnifications proved very deceptive. Several of the figures illustrate the mistakes most easily made in counting the number of layers of cells.

Figure 1 is a camera-lucida drawing of a portion of one of the sections from the distended bladder no. 1. At lower magnifications one would readily suppose that, counting down from the large surface cell, at the point indicated by the arrow, there were in all three layers. But at higher magnifications it is clearly seen that there is a junction of the two cells lying beneath this surface cell, and that there is a cut edge of a basal layer cell just above the nearest connective-tissue nucleus; so the number of layers in this region is five. Focusing down, the slip seen at the base in the focal plane of the drawing develops into a nucleated cell.

The method of counting nuclei was not found serviceable in determining the number of layers at any given focal plane. This is shown in figure 2, which is a camera-lucida drawing of a

portion of a section of the distended bladder no. 3. If one depended upon the nuclei, the number of layers would vary between two and one. But here again the edges of cells cut outside of their nuclei make the variation one between three and four layers. It should also be mentioned that if a line is drawn perpendicular to the surface of the epithelium at (*a*), it passes through four cells,

1



2

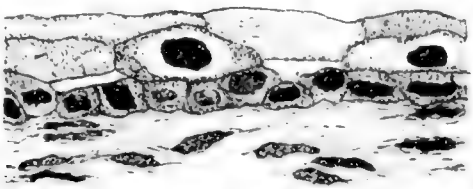
Fig. 1 Camera-lucida drawing of portion of epithelium of distended bladder no. 1 (×1128). The arrow marks the point at which the five-layered epithelium is easily mistaken for a three-layered one.

Fig. 2 Camera-lucida drawing of portion of distended epithelium of bladder no. 3 (×1128). The layers of nuclei vary between one and two. Actual layers of cells vary between three and four.

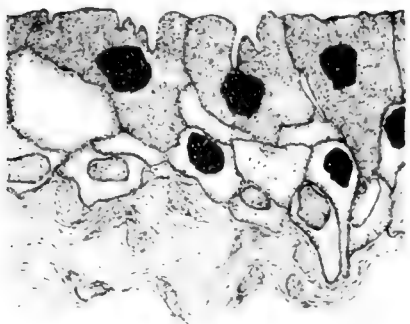
but the number of layers is really only three, since the last two cells through which the line passes are really in the same layer, the boundary between them being diagonal.

Figure 3, a camera-lucida drawing of portion of the epithelium of distended bladder no. 1, again emphasizes the fact that in this series of studies the method of counting nuclei had to be aban-

doned, because the number of layers of cells was the information desired. It also presents another example of the importance of counting cells whose cut edges might easily escape notice at low magnifications. In the region (A) the epithelium might easily be mistaken for a two-layered one, because the small cut edge of a second layer cell and the surface cell are about equally granular



3



4

Fig. 3 Camera-lucida drawing of portion of the distended epithelium of bladder no. 1 (× 705). The figure shows the importance of counting portions of cells not containing nuclei, such as those in the region A, when estimating the number of layers.

Fig. 4 Camera-lucida drawing of portion of the epithelium of contracted bladder no. 6 (× 705). This figure shows two places at which the contracted epithelium is only two layers thick.

and appear about the same shade. But a fine, distinct cell boundary separates them.

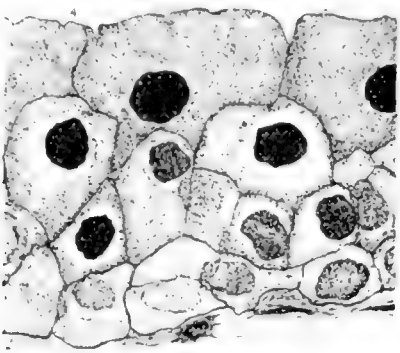
When all these precautions are observed, there will still be some points where the distended epithelium appears to be only two layers thick. But, turning to the bladders that have contracted to the point where folds just begin to form, we will find

quite as many places where the epithelium is only two layers thick. Figure 4 shows a piece of contracted epithelium, and at two places in the figure there are only two layers of cells.

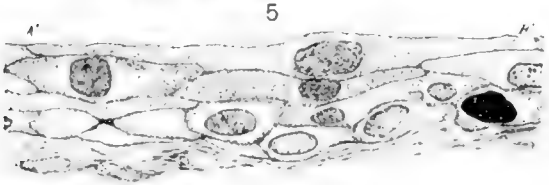
There is evidence that the cells in the epithelium are bound to their neighbors pretty firmly. If one examines the various figures of contracted and distended epithelium shown in this paper, it is noteworthy that in the distended bladders the cells are still bound to their lateral neighbors along a considerable distance. In the surface layer these boundaries between cells may run perpendicular to the surface or at almost any other angle, but the length of the boundary bears about the same relation to the greatest thickness of the distended cells as the lengths of the boundaries between surface cells in the contracted epithelium bear to the greatest thickness of the cells in contraction. The surface cells with basal processes are also interesting objects in this connection. Figures 5 and 6 show portions of two bladders, one in contraction and one in distention, in which there is a comparable, though not identical relation of such cells. The three cells in the second layer, in the region between (*A'*) and (*B'*) of figure 6, bear about the same relation to the large surface cell in this region as the three second-layer cells in the region between (*A*) and (*B*) in figure 5 bear to the contracted surface cell with the basal processes. And the significant point in the figures is that the surface cell in figure 6, though distended to the great length of 95.7μ still has points along its lower border that suggest remnants of basal processes. Considering the degree of distention of this surface cell, one would expect its lower boundary to be more nearly straight, if there were not a firm attachment of the lower cells that exerted a tension at the two points where the most marked irregularities exist.

Sections of the extensively folded epithelium of completely contracted bladders are also interesting subjects for study. On the crest of a fold, a section through the epithelium will frequently have the appearance shown in figure 7. The appearance of the surface cells is that of partial distention, as though they had been stretched by the pushing in of the fold.

In the bottom of the pits, or rather troughs, between folds, the cells frequently have a columnar appearance. This is shown in figure 8. In the middle of the piece of epithelium shown, this columnar appearance is not only apparent, but real, while at the borders the figure is misleading, because the epithelium is rotated through ninety degrees from the position in which it is usually figured.



5



6

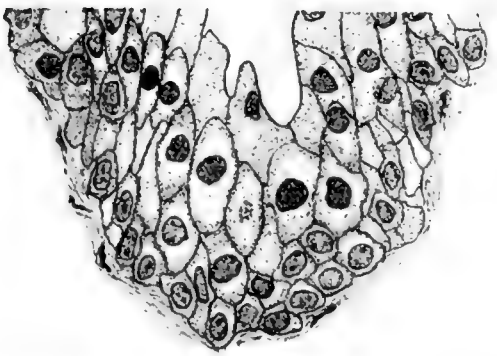
Fig. 5 Camera-lucida drawing of portion of the epithelium of distended bladder no. 6 (× 705). The surface and second-layer cells in the region between *A* and *B* bear a relation to one another similar to that of the corresponding cells in figure 6, in the region *A'* to *B'*.

Fig. 6 Camera-lucida drawing of portion of the epithelium of distended bladder no. 3 (× 705). Note the projections on the lower surface of the large surface cell, suggesting remnants of basal processes.

The first method of approaching the problem under discussion — the method of simply counting the number of layers of cells in any given focal plane — therefore results in the conclusion that the range of variation in the number of layers in the contracted bladder is about the same as in the distended bladder. The usual number of layers in both is three to four, and in either

contracted or distended bladders there may be places where there are only two layers or where there are more than four. This method of stating results still does not give completely the information desired, for the question remains: Does the contracted bladder contain more area covered by four layers and the distended bladder more area covered by three layers? If there is

7



8

Fig. 7 Camera-lucida drawing of the epithelium at the crest of a fold in completely contracted bladder no. 2 (× 422). Note the partially distended appearance of the surface cells.

Fig. 8 Camera-lucida drawing of the epithelium in a trough between folds of completely contracted bladder no. 2 (× 422). Note the columnar appearance of the cells.

such a difference, it is not so noticeable as to be at once agreed upon after studying two comparative sections. So at this point the second method of inquiry, depending upon cell measurements is brought in.

METHOD OF CELL MEASUREMENTS, AND ITS RESULTS

It is evident that if all of the stretching of the epithelium is to be accounted for by stretching of the cells, and not by 'slipping' or rearrangement into fewer layers, the ratio that represents the stretching of the epithelium in any given direction should be identical with the ratio that represents the stretching of the cells in this direction.

The amount of stretching of the epithelia was determined as follows: After fixing, as stated before, an equatorial zone, 3 to 5 mm. wide, was cut from the distended bladders and from those that had contracted to the point where folds just began to form. These zones were cut open along any meridian, thus converting them into ribbons, the length of which, measured just before imbedding, gave accurate results as to the length of the epithelium in the completely distended bladders. The ribbon-like strips were then cut into a convenient number of pieces, all of which were imbedded. Sections were cut perpendicular to the surface of the epithelium and parallel to the equator of the bladder. By projecting a section from each block of any particular zone, and measuring it with a wheel tracer, the length of the complete epithelium i.e., the circumference of the circle which it forms in a complete section perpendicular to the long axis of the bladder at the equator—was calculated.

The lengths of the cells were then measured, in the direction parallel to the surface of the epithelium, in the same sections. It is evident that if there has been no slipping, the ratio of contracted to distended cells should be the same as that of contracted to distended epithelium. It must be borne in mind that the quantities here compared are linear quantities, and not areas, and that like dimensions, and not squares of like dimensions, are therefore compared.

Completely contracted bladders cannot be compared with greatly distended ones by this method, because of the impossibility of obtaining accurate information in regard to the length of the epithelium in the completely contracted bladder. When the folds of the epithelium first form, they are fairly regular

longitudinal, or rather meridional, folds. But on further contraction they become very irregular, probably due to the fact that the longitudinal muscle layer, contracting, carries with it the tunica propria that runs into these already formed folds. Figure 9 illustrates this point. It is a sketch of a portion of the epithelium of a completely contracted bladder in surface view. The bladder was found completely contracted in a freshly killed adult rabbit. Base and apex were cut off, and the bladder was

9

Fig. 9 Free-hand drawing of epithelial surface of completely contracted bladder (× 7.5). The vertical direction of the drawing is meridional with respect to the bladder. The figure shows that transverse sections may pass through the same fold three times.

cut open along a meridian. It was then spread out flat, with the epithelium uppermost. The corners were pinned down, and the specimen hardened in bichloride solution. A small square piece was cut out and sketched. The vertical direction of the drawing as here shown is longitudinal with respect to the bladder. It is easily seen that a section running at right angles to the long axis of the bladder might cross the same irregular longitudinal fold three times. Consequently, when the sections are studied, it is impossible to decide whether a given fold has been produced

by meridional or by equatorial contraction. To measure the length of the surface of the epithelium in sections across a completely contracted bladder is therefore useless. This was noticed during the preliminary work on this problem. The length of the contracted epithelium, multiplied by the amount of stretching observed in the cells, far more than accounted for the length of the distended epithelium. This was true even though all masses of epithelium within the main lumen, or all separate portions of the lumen not connected with the main lumen in the section, were left out of consideration.

The measurement of the length of the cells parallel to the surface of the epithelium was done with a micrometer eyepiece. It is essential that some method be employed which will result in representing all parts of a given circumference, and prevent undue choosing of certain types of cells that one comes to think of as typical. For example, one may take every cell in a given layer that has a nucleus and clearly defined boundaries, or every second or third cell of this description, according to the number of cells desired. The variation from cell to cell, in the same region, and from one part of the circumference to another, is very great. The largest cells may be six to ten times longer than the smallest. The first hundred cells in any given layer of a section, on the other hand, may be one and one-fourth times the size of the second hundred in the same section. But if the average of three hundred or more cells representing all parts of a given circumference is taken, and the measurements repeated in different sections from the same bladder, using the same method, the results will be nearly identical. So the method of taking every cell in a given layer, having a nucleus and clearly defined boundaries, and comparing the average size with that of cells similarly chosen from another bladder is an entirely reliable method of comparison. In the case of cells that have the shape of a parallelogram, the length of the side parallel to the surface of the epithelium is taken as the length of the cell.

The results obtained from several measurements of each epithelium, and about six thousand cell measurements, in material from the six rabbits, were as follows (table 1):

TABLE 1

Bladder no. 1 (distended)

Length of epithelium ..... .8 cm.

Length of cells:

		Average
1st (surface) layer	470 cells	51.4μ
2nd layer	385 cells	32.4μ
3rd layer	330 cells	18.8μ

Bladder no. 2 (completely contracted)

Length of epithelium ..... measurement impossible.

Length of cells:

1st layer	386 cells	27.6μ
2nd layer	275 cells	18.3μ
3rd layer	220 cells	10.1μ

Bladder no. 3 (partially distended)

Length of epithelium ..... 6.5 cm.

Length of cells:

1st layer	345 cells	46.2μ
2nd layer	385 cells	29.9μ
3rd layer	330 cells	18.9μ

Bladder no. 4 (completely contracted)

Length of epithelium ..... measurement impossible.

Length of cells:

1st layer	220 cells	27.7μ
2nd layer	220 cells	18.8μ
3rd layer	220 cells	9.6μ

Bladder no. 5 (contracted to beginning folding)

Length of epithelium ..... 3.8 cm.

Length of cells:

1st layer	393 cells	26.0μ
2nd layer	440 cells	17.6μ
3rd layer	330 cells	10.5μ

Bladder no. 6 (contracted to beginning folding)

Length of epithelium ..... 3.7 cm.

Length of cells:

1st layer	294 cells	25.9μ
2nd layer	385 cells	17.1μ
3rd layer	330 cells	10.8μ

Bladders no. 2 and no. 4 were completely contracted, so the length of epithelium is not entered for reasons previously stated. If we compare the contracted bladders no. 5 and no. 6 with the distended bladders no. 1 and no. 3, and find the ratio between the lengths of the epithelia and between the lengths of the cells of each layer, we obtain the following ratios (table 2):

TABLE 2

	RATIOS OF			
	No. 1 / No. 6	No. 1 / No. 5	No. 3 / No. 6	No. 3 / No. 5
Lengths of epithelia	2.16	2.10	1.75	1.71
Lengths of cells:				
1st layer	1.98	1.98	1.78	1.77
2nd layer	1.89	1.84	1.74	1.70
3rd layer	1.74	1.79	1.75	1.80

The significance of these results will now be discussed.

In the first place, it is evident that no great change in the length of the cells, measured parallel to the epithelial surface, occurs after folds have begun to form. The epithelia of bladders no. 2 and no. 4 were completely contracted and complexly folded. Nos. 5 and 6 were contracted to the point of beginning folding. Comparing the sizes of the cells, there is little difference. The surface cells (first layer) of nos. 2 and 4 are even slightly larger than those of nos. 5 and 6, probably because of the stretching at the crests of folds spoken of previously and illustrated in figure 7.

Secondly, the ratios between bladders no. 3 and no. 6 and between no. 3 and no. 5 show that there is no indication whatever of slipping of cells. The cells in bladder no. 3 have been stretched just as much as the epithelium. It must be borne in mind that 6.5 cm. represents the equatorial length of the epithelium of bladder no. 3 after fixing and dehydrating. In the fresh condition it measured 8.2 cm., so that the diameter at this point, or transverse axis, as it is sometimes called, was 2.6 cm. At this stage in distention the transverse axis is considerably shorter than the long axis, so that this bladder was well distended.

Thirdly, we notice that in comparing bladder no. 1 with nos. 5 and 6, the ratios indicating the stretching of the cells all fall short of the ratio indicating the stretching of the epithelium, and that they fall progressively shorter from the surface layer to the third layer. If bladder no. 3 is regarded as partly contracted, with reference to bladder no. 1 and the ratios determined, the same variation will again be established, so that bladder no. 1 is compared with three comparable bladders, with practically identical

results in every case. Still, the amount that the surface cells fall short is very small, and may be accounted for by the fact that as one measures the surface cells that have nuclei and clearly defined cell boundaries, fewer large cells than small cells conform to this standard. If the ratio is correct, it would mean that a piece of the surface layer that contained 198 cells in contraction contained 216 in distention, or that every twelfth cell in the surface layer of the distended bladder had crept in from a lower layer. The widest divergence is obtained by comparing the third layers of bladders 1 and 6. The cells of the third layer of no. 1 are 1.74 as long as those of no. 6, while epithelium no. 1 is 2.16 as long as that of no. 6. This means that a piece of the third layer that in contraction contained 174 cells in distention contained 216, or that every fifth cell, approximately, in the distended condition had entered the layer from another layer. If one imagines this, the greatest divergence found, occurring in each layer of five layered epithelium, it would be just sufficient to reduce the layers from five to four. The exact amount of rearrangement of cells indicated by taking into account all the ratios tabulated in comparing bladder no. 1 with bladders no. 5 and no. 6 would be a change from a four-layered epithelium in contraction to a 3.5-layered one in distention, or a five-layered one in contraction to a 4.4-layered one in distention. And this distention was a large one, for the circumference of the bladder before fixing was 10.4 cm. at the equator, which compares favorably with the greatest distentions seen in rabbits of twice the weight of this one, though more than a score of autopsies of such rabbits were taken note of.

Measurements similar to those above tabulated and discussed were also made on three bladders from adult rabbits. These rabbits were of the same litter, weighed a little more than 5 pounds each, and had been used for experiments in connection with studies on the development of bone.

The bladder of rabbit no. 8 was found contracted to the point where folding of the epithelium just begins. Rabbit no. 9 had a partly distended bladder. Rabbit no. 10 was played with for three-quarters of an hour, then anaesthetized with ether. The

abdomen was opened, and the bladder was found greatly distended. Its shape approached the spherical, as is the case in complete distention. Its equatorial circumference was 9.5 cm. before fixing. The technique employed was identical with that previously described.

The epithelia of these bladders had, on an average, nearly one layer of cells more than those of the previous series. Measurements were made of cells of three layers, and also of those basal cells situated between the tapering ends of cells which, though of the next higher level, also reach the basement membrane. The results were as follows (table 3):

TABLE 3

Bladder no. 8 (contracted to beginning folding)		
Length of epithelium		4.2 cm.
Length of cells:		Average
1st layer (surface)	477 cells	29.1μ
2nd layer	440 cells	20.0μ
3rd layer	330 cells	14.9μ
Basal cells	330 cells	9.7μ
Bladder no. 9 (partially distended)		
Length of epithelium		5.9 cm.
Length of cells:		
1st layer	440 cells	52.4μ
2nd layer	440 cells	28.6μ
3rd layer	316 cells	22.4μ
Basal cells	220 cells	12.5μ
Bladder no. 10 (distended)		
Length of epithelium		7.5 cm.
Length of cells:		
1st layer	427 cells	67.3μ
2nd layer	330 cells	33.7μ
3rd layer	330 cells	24.7μ
Basal cells	330 cells	14.4μ

A few ratios will suffice to point out the significance of these results (table 4):

In comparing the completely distended bladder with the contracted and with the partly distended one, therefore, the ratios obtained for the cells diminish in value from surface to base as

they did in the previous series. Comparing them with the ratios for the epithelia, the only striking irregularity and by far the largest of its kind in either series, is found in the ratio of the first layer cells of bladders 10 and 8. Here the stretching of the cells far more than accounts for the stretching of the epithelium. Comparing bladder no. 9 with bladder no. 8, we find a similar divergence. This means, no doubt, that bladder no. 8 had unusually small surface cells, while bladders no. 9 and no. 10 were comparable. The ratios in the middle column are therefore the important ones. The ratios in this column, taken together, indicate that the number of layers was diminished by 7.4 per cent

TABLE 4

	RATIOS OF		
	No. 10 / No. 8	No. 10 / No. 9	No. 9 / No. 8
Lengths of epithelia	1.78	1.27	1.40
Lengths of cells:			
1st layer	2.31	1.28	1.80
2nd layer	1.68	1.17	1.43
3rd layer	1.65	1.10	1.50
Basal cells	1.48	1.15	1.28

during distention, while those in the previous series indicated a maximum of 12.5 per cent diminution.

The possibility of cells 'slipping by one another' is therefore not eliminated. But it is evident that the decrease in layers, if present, is far less than the first glance at sections of contracted and distended bladders would suggest. Very slight tangency will increase the number of apparent layers when the cells are tall, as in contraction, whether the epithelium is folded or not. And this, with the thinness of the distended cells, accounts for the illusion.

Just what is meant by 'slipping by one another' is seldom mentioned. The only thing it could mean, so far as these studies suggest, may be shown by reference to figure 1. Beneath the only nucleus in the first layer is the junction of the two nucleated second-layer cells. If, on further distention, these two cells

should lose their attachment to each other, the cell just beneath would touch the surface cell, and the number of layers be reduced by one. The two second-layer cells might still maintain their attachment to the surface cell and to the cell between and beneath them, so that the integrity of the epithelium would not be endangered. Both histological study and the ratios above given suggest that such occurrences are more possible in the lower layers than in the surface layers, for in the latter the appearance of the cells suggests that they are bound very firmly to their lateral neighbors. Some of the basal cells are so imbedded in the basement membrane that this perhaps determines their position quite as much as attachment to the neighboring cells.

Turning again to figure 1, however, it is easy to see that a little more distention would cause the lower boundary of the nucleated surface cell, the connection between the second layer cells, and the upper boundary of the third layer cell to stain as one black line for a short distance. The interpretation of the microscopic picture would then become a matter of opinion. In the range of distentions above studied, which certainly equaled the range of normal physiological distention, there was little need for speculation, however, and the desired measurements could readily be made at a magnification of 950.

It is interesting to note that during the measurement of the first 6000 cells, which brought under observation several times that number, only one mitotic figure was observed, and this was in the layer next above the basal layer. During the measurement of over 4000 cells in the second series several mitotic figures were observed, and surface cells with two, three, or four nuclei were more frequent than in the first series.

Cuticular borders were not in evidence in these specimens, which were fixed in bichloride, and were in the final fixing solution within ten minutes after the death of the animals.

DISCUSSION

London, in 1881, studied bladder epithelium in contraction and distention in connection with the problem of resorption. He used bladders from dogs, and tried at first to distend them immediately after removal by forcing the fixative into the interior. This method he abandoned, because the prepared specimens showed a torn epithelium that he attributed to hardening of the epithelium by the fixative while distention still continued. He therefore distended the bladders by surrounding them with a negative pressure while ureters were left open at atmospheric pressure, and filled and surrounded them with fixative after the desired distention had been reached. He also used the method of fixing bladders with urine left inside to avoid contraction, but left the urine in these bladders twenty-four hours. His principal conclusions were: 1) that the thickness of the epithelium and all the layers of the bladder wall increases with age and size of the animal, and perhaps also with developed habits of retaining urine, as in the case of house dogs; 2) that the volume of the epithelial cells, or the entire epithelium, is the same in distention as in contraction, or that the thickness of the epithelium varies inversely as the area; 3) that the diminution of layers in distention is apparent, because of the diminution of layers of nuclei, but is not real if cell boundaries are taken into consideration. His closing statement that the epithelium possesses greater elasticity during contraction than during distention is very peculiar, unless we regard the epithelium as active rather than passive in contraction and distention, and ascribe to the cells changing conditions of tone. London's method of telling whether a section is tangent or not by noting whether the outline of the surface of the epithelium shifts on focusing is not infallible. The figures in this paper show that even the distended epithelium, when fixed, possesses irregularities, such as bulgings over nuclei in the surface layer, and other elevations and depressions. If a section, perpendicular to the general direction of the epithelial surface, includes one of these irregularities, the outline of the surface will shift on focusing. And in bladders fixed in contraction

each cell bulges into the lumen, presenting a spherical surface, so that the free surface outline will shift on focusing, regardless of whether the section is tangent to the general direction of the epithelium or not. Whether the thin lines London describes and interprets as cell boundaries of cut edges of cells were the same as the boundaries of cells without nuclei shown in the above figures is not certain. The above figures represent conditions in any one focal plane, and since the sections were 10μ thick, the narrow edges of cells shown could be traced to wider portions on focusing, or, in the lower layers, to the nucleated portion of the cell.

Dogiel ('90) studied the histology of the contracted bladder epithelium, especially of rodents, but also of dogs, cats, and man. He quotes Oberdieck as saying that in distention the surface cells flatten, while the deeper cells are displaced from their positions. He also cites Oberdieck's statement that bladder epithelium, in general, may be considered as three-layered epithelium, and in his own work distinguishes four layers—a surface layer whose cells are thick platelets, and whose shape, seen in surface view is irregularly polygonal; a second layer of irregular cylindrical or cubical cells, with long axis perpendicular to the epithelial surface; a third layer of somewhat cylindrical cells, the end nearer the epithelial surface being club-like and the opposite end tapering and reaching the basement membrane; a fourth layer of round, oval, or fusiform cells occupying the spaces between the narrowed lower ends of the third-layer cells. He made extensive studies of cells in macerated specimens. The surface cells are said to consist of an outer homogeneous third, and a deeper granular two-thirds, containing the nucleus or nuclei. The outer homogeneous portion (cuticular border) separates on maceration, and is claimed to be of a mucoid nature. The granular appearance of the cytoplasm is attributed to fibrillar protoplasmic network. Dogiel further claims to have demonstrated, and figures an extensive system of interlocking of the cells of the first two layers of epithelium, by projections of the second-layer cells fitting into depressions of the lower surface of the surface cells, and says that through these interlockings protoplasmic fibrils extend from

one cell to another. On this basis he founds his conclusion that these first two layers of cells permit of no rearrangement whatever and merely flatten in distention. This conclusion would be defensible only if an equally valid system of interlocking were demonstrated for the second-layer cells in their relations to one another, for, as shown in the discussion of the term 'slipping by one another' in connection with the cells of figure 1 above, it is shown that a cell need not lose all hold of its surroundings in order to part with the nearest neighbor in the same layer. The existence of the large projections of the second-layer cells that fit into depressions in the bottom of the first-layer cells is questioned by other observers, who used mainly dog material. Dogiel emphasized their prominence especially in material from small rodents, such as rats and mice. If they are sufficiently numerous in rabbit bladders to be of essential importance, they should be seen more frequently in sections, since a 10μ section takes in about half of a contracted second-layer cell. In the first series of bladders studied above, these projections were not seen at all. In the second series they were found occasionally. Wherever found, they were very definite structures. Whether fibrils extended from one cell to another could not be determined, because a definite cell boundary separated the cells. Dogiel describes these structures from macerated specimens. Harvey, in studying macerated preparations of bladder epithelium of dogs, did not corroborate these findings. He describes the cells as having a regular outline, and finds no structures or projections similar to those of Dogiel that could not be more readily considered products of maceration.

Eggeling ('01) studied the histology of the surface layer of bladder and ureter and reviewed the literature on the subject. He notes the recorded variability of a cuticular border in ureters from different animals and with various fixatives, which showed gradations from practical absence to virtual cornification of the entire surface layer. A description of the cuticular border, as demonstrated after alcohol-chloroform-acetic-acid fixation follows, and its significance in protecting the epithelium from contact with urine and in preventing or reducing resorption is dis-

cussed. The existence of canals in the epithelium, described by Lendorf, is not corroborated, and the evidence of secretory activity of the surface cells is considered doubtful.

To each of these articles a large bibliography is appended, but the subjects treated deal mainly with the histology for any static condition -studies on channels in epithelia, studies on goblet cells, etc.—and do not relate to distention.

Harvey, in 1909, published an interesting article on variations in the wall of the bladder and ureter in contraction and distention. He used dogs, and distended the excised bladders by forcing in Zenker's fluid. Staining was done with hematoxylin and congo-red. Cell boundaries are described as distinct only in the contracted bladder and in the surface layer of the distended. In the other layers of the distended bladder they are "discontinuous or in fragments, as though the cytoplasm of adjacent cells had fused in places, or distention has made the membranes so thin as to be invisible." The nuclei are depended upon in this inquiry into the relations that cells assume in contraction and distention, as in the earlier work of Herzog. In regard to bladder epithelium, the following conclusions are reached 1) that the distended epithelium is one-sixth the thickness of the contracted; 2) that the number of layers of nuclei is decreased 50 per cent, approximately, in distention; 3) that there may be, in addition to the stretching of cells, a slight displacement of the cells from their relative position, hence, an actual diminution of the number of layers.

The diminution in the number of layers of nuclei is interesting. The first conclusion above tabulated, together with the work of London, which showed that the volume of the epithelium in distention is the same as that in contraction, show that the surface of the epithelium distended by Harvey increased six times. A line perpendicular to the epithelium at any point would have a sixth as many chances of piercing nuclei in the distended bladder as it would have in the contracted. And a plane, passing entirely through the contracted and distended bladders at comparable points would have 2.4 the square root of six—times the number of chances of encountering nuclei in the contracted bladder that

it would have in the distended, if the nuclei remained unchanged in size. But they do not. Measurement of 110 nuclei of contracted bladder no. 6 of the above series, and 110 nuclei of the distended bladder no. 1 showed that while the epithelium had been stretched along the equator to 2.1 times its former length, the nuclei had been stretched to 1.14 times their former diameter parallel with this direction. If a stretching of 2.1 times increased the diameter by 0.14, a stretching of 2.44, as in Harvey's work, would probably increase it to 1.16 times its former length. This would counteract the effect of increasing distances between the centers of nuclei, so that a plane having a chance of passing through 244 nuclei in the contracted bladder would pass through 116 in the distended. This amounts to a 52.4 per cent decrease, or very nearly the percentage decrease established by Harvey in counting the layers of nuclei in a given focal plane.

SUMMARY

The results of this investigation, so far as the principal problem stated at the beginning is concerned, may be summarized as follows:

1. Moderate physiological distention of the rabbit's bladder is reached without any evidence that the cells of the epithelium are displaced from their relative positions, that is, without any decrease in the number of layers.

2. Very great physiological distention of the rabbit's bladder probably results in a slight decrease in the average number of layers. This decrease is scarcely demonstrable without making cell measurements, and these show that it does not amount to more than 12.5 per cent.

3. Histological evidence and measurements confirm the idea that the cells of the epithelium are bound to one another more firmly in the first and second layer than in the third or deeper layers.

It is obvious that the conclusive data cover only the range of distention and contraction that lies between beginning folding of the epithelium and maximum physiological distention. Whether the cells form more layers in complete contraction is not known.

All that is shown is that they do not contract further after folds have begun to form.

In conclusion, I wish to acknowledge my indebtedness to Dr. E. R. Clark, under whose direction this investigation was carried out.

Resumen por el autor, W. N. Hess,
Cornell University, Ithaca.

Tráqueas en los órganos luminosos de algunos Lampíridos comunes.

Comparando los principales troncos traqueales y sus ramificaciones mas importantes en los segmentos abdominales de algunos de nuestros mas comunes lampíridos, el autor ha encontrado que la disposición de estas ramificaciones es semejante en cada segmento abdominal excepto en el noveno, y que no existen nuevas ramificaciones en adición a los principales troncos traqueales. La principal diferencia consiste en el excesivo tamaño de los troncos principales y sus ramificaciones en los segmentos en que están colocados los órganos luminosos. Aun cuando no nacen nuevas ramificaciones en los troncos principales, las que existen son mas gruesas y parecen dividirse mucho mas frecuentemente en ramillas mas y mas finas, que las que existen en otros segmentos abdominales, con el fín de aportar mayor cantidad de aire a los órganos luminosos.

En los machos de nuestros lampíridos mas luminosos algunos de los conectivos longitudinales de las tráqueas situadas en los segmentos que contienen los órganos productores de luz, en vez de unir entre si los troncos traqueales de estos segmentos, se han dividido y ramificado considerablemente, conduciendo directamente el aire a los órganos luminosos.

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED
BY THE BIBLIOGRAPHIC SERVICE, NOVEMBER 15

TRACHEATION OF THE LIGHT-ORGANS OF SOME COMMON LAMPYRIDAE[1]

WALTER N. HESS

TEN FIGURES

The light-organs of all the luminous fireflies that have been described occupy a part, or the entire ventral portion, of one or more abdominal segments. In a large per cent of luminous males the organs occupy the entire ventral portions of the sixth and seventh abdominal segments, while not infrequently the organs of the females are much smaller and restricted to a small area in the sixth segment. In our luminous larvae the organs are usually paired and lie in the ventro-lateral portion of the eighth abdominal segment.

The structure of the light-organs in all insects that have been studied, whether in the larva, pupa, or adult, appears to be very similar. They have always been found to consist of an inner, non-photogenic layer called the reflector and an outer luminous, or photogenic, layer (figs. 1 and 2).

The author is indebted to Dr. William A. Riley, under whose direction this study was made, for his helpful suggestions and criticisms.

Numerous workers have studied the structure of the mature light-organs, and in this connection many have figured the arrangement of the tracheal end-cells within the organ itself. Yet so far as any detailed study of the arrangement of the main tracheal trunks and branches that supply the light-organs is concerned, nothing seems to have been done except a brief work by Geipel ('15). He figured, in a semidiagrammatic way, their arrangement in the male of Luciola africana. According to his

[1] Contribution from the Entomological Laboratory of Cornell University.

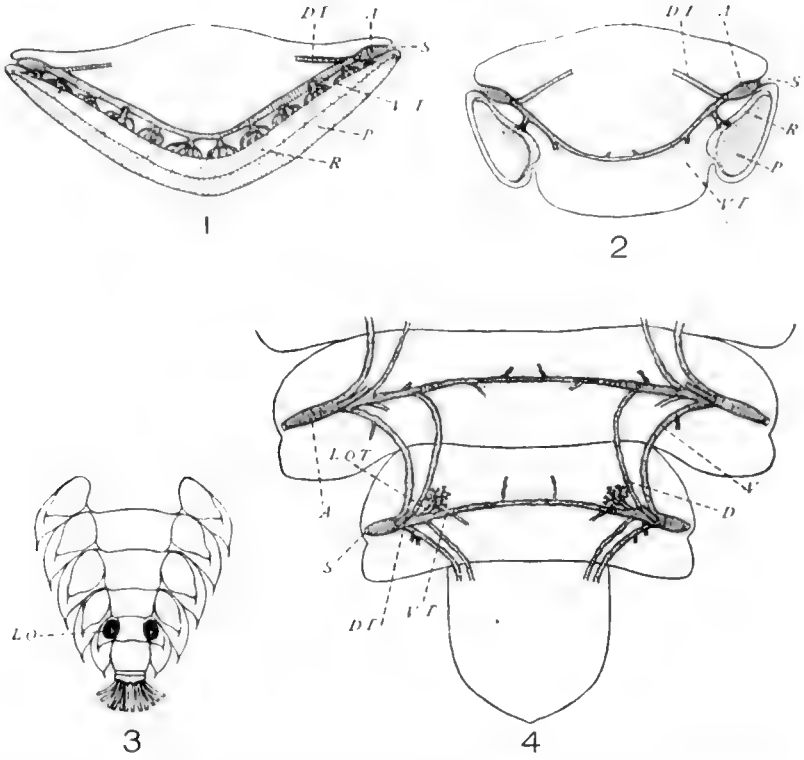

Fig. 1 Photinus scintillans, male, diagrammatic drawing to represent the two layers of the light-organ and the general arrangement of the larger trachea. *A*, ampulla; *D T*, dorsal tracheal trunk; *P*, photogenic layer; *R*, reflector layer; *S*, spiracle; *V T*, ventral tracheal trunk.

Fig. 2 Photurus pennsylvanica, larva, diagrammatic drawing to show the two layers of the light-organ, and the arrangement of the trachea. *A*, ampulla; *D T*, dorsal tracheal trunk; *P*, photogenic layer; *R*, reflector layer; *S*, spiracle; *V T*, ventral tracheal trunk.

Fig. 3 Photurus pennsylvanica, larva, ventral view of abdomen. The dark elliptical areas which are located on the eighth abdominal segment represent the larval light-organs, *L O*.

Fig. 4 Photurus pennsylvanica, larva, dorsal view of the principal trachea of the seventh and eighth abdominal segments. *A*, ampulla; *D*, dorsal longitudinal tracheal connective; *D T*, dorsal tracheal trunk; *L O T*, light-organ trachea; *S*, spiracle; *V*, ventral longitudinal tracheal connective. All tracheae shown with small branches supply the light-organ.

description, the main tracheal branches arise irregularly from the ventral transverse tracheal connectives.

In order better to understand the general relation of the tracheal trunks and their branches which supply oxygen to the light-organs of the adult and larva, a diagrammatic drawing was made of a cross-section through the seventh segment of a male of Photinus scintillans (fig. 1), and through the eighth abdominal segment of the larva of Photurus pennsylvanica (fig. 2). Both figures readily show the dorsal and ventral tracheal trunks which separate from the ampulla near the spiracle. In the case of the adult, the ventral trunk gives off numerous branches, which soon divide, sending their little tubes into the light-organ. These tubes pass through the reflector layer into the photogenic layer where they end in numerous tracheoles. The light-organs of the larva, however, are each supplied by one large tracheal branch, which leaves the ventral trunk near the ampulla. As it enters the light-organ it divides profusely, sending its branches throughout the region of the photogenic layer (*P*).

In the larva of Photurus pennsylvanica (fig. 3, *L O*) the light-organs appear externally as two small oval areas on the ventro-lateral sides of the eighth abdominal segment.

Since it was found that the arrangement of all the main tracheal branches in the different abdominal segments of the larva, except the ninth, are similar to those shown in the seventh and eighth segments (fig. 4), the trachea of only these two segments were figured. As can be readily seen by a comparison of the tracheation in these two abdominal segments, the branches arising from the transverse trunk in each segment are similar and they are bilaterally arranged. The trachea which supply oxygen to the light-organs in segment eight are simply enlarged branches which arise from the ventral transverse tracheal connective (*V T*) and correspond to similar branches which arise from the ventral transverse tracheal connective in segment seven. The branch from the ventral tracheal trunk in segment eight which supplies the light-organ (*L O T*) is shown with many of its branches.

The adult female of Photurus pennsylvanica, which is one of our largest native luminous fireflies, has the light-organs restricted

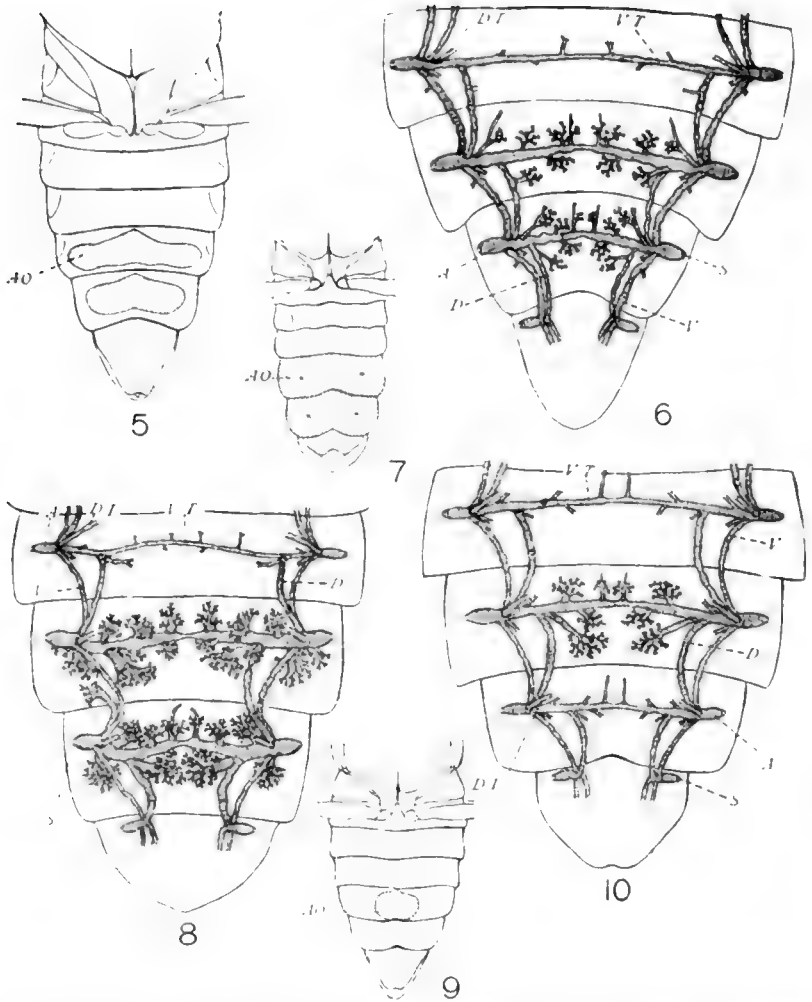

Fig. 5 Photorus pennsylvanica, female, ventral view of abdomen. The stippled areas on the sixth and seventh abdominal segments represent the adult light-organ (*A O*).

Fig. 7 Photinus scintillans, male, ventral view of abdomen. The stippled areas on the sixth and seventh abdominal segments represent the adult light-organ (*A O*).

Fig. 8 Photinus scintillans, male, dorsal view of the principal trachea of the fifth, sixth, and seventh abdominal segments. For labels see figure 4.

Fig. 9 Photinus scintillans, female, ventral view of abdomen. The shaded area on the sixth abdominal segment represents the adult light-organ (*A O*).

Fig. 10 Photinus scintillans, female, dorsal view of principal trachea of the fifth, sixth, and seventh abdominal segments. For labels see figure 4.

to an area covering about two-thirds of the sternites of the sixth and seventh abdominal segments (fig. 5, *A O*). These organs are supplied with branches that arise from the ventral transverse tracheal connectives of the sixth and seventh abdominal segments, which are shown with their many branches (fig. 6). The arrangement of the tracheal branches in both segments is the same, and these branches correspond to similar trunks found in segment five, as well as to those in the other anterior abdominal segments. These trunks are much smaller than they are in the male, due to the fact that the organs are smaller, and hence they do not require as large an air supply.

The tracheation of the light-organs of the male Photurus pennsylvanica was not figured, as it was found to be similar to that of the male of Photinus scintillans, which will be discussed.

The adult male of Photinus scintillans, like most of our other luminous males, has its light-organs extensively developed so that they cover the entire sternites of the sixth and seventh abdominal segments (fig. 7, *A O*). The main tracheal trunks of this insect in the sixth and seventh abdominal segments were found to be of immense size (fig. 8), in order to supply the large amount of air that is needed by these light-organs. A brief description of these enlarged trunks will readily show the extreme of tracheal specialization for the supply of air to the light-organs of fireflies. The arrangement of the tracheal branches which arise from the ventral transverse tracheal connective of segment six is practically identical with the arrangement of the branches which arise from the corresponding trunk in segment five. The chief difference is that they are larger and the finer branches appear much more numerous. The arrangement of the branches in the sixth abdominal segment correspond very closely to those in the seventh abdominal segment. The longitudinal tracheal connectives between these two segments have a tendency to become modified into branches which supply the tissues of the light-organs, but no new branches were found to arise from the transverse tracheal connective of either segment. In the specimen that was figured the ventral longitudinal tracheal connective (*V*) between segments six and seven, on the left side, is not

continuous, but has divided near the middle, and has become much branched for the purpose of supplying air to the light-organs. On the right side this connective, in the specimen which was drawn, was found to be very narrow, and at one point it showed evidence of a tendency to divide. The ventral transverse tracheal connectives in segments six and seven are very large from the spiracles to the center of the body. Here they become the same size as corresponding trachea in the other abdominal segments. In no case are accessory branches found to arise from the ventral transverse tracheal connectives, but the branches frequently divided and subdivided into numerous smaller branches, as soon as, or soon after, they arose from the main transverse trunks. A small amount of air for the light-organs evidently enters the spiracles of the fifth and eighth abdominal segments as certain of the longitudinal tracheal connectives leading from these segments to those of the light-organs are larger than in the other segments.

The female of Photinus scintillans, which has a very small light-organ in the sixth abdominal segment (fig. 9, *A O*) naturally has a reduced air supply. The main tracheal trunks of the sixth abdominal segment are somewhat enlarged (fig. 10), but they are small in comparison with the corresponding trunks in the male. As is also true of the other fireflies studied, no new tracheal branches are found to arise from the ventral transverse tracheal connectives, but these branches divide into numerous smaller branches in the region of the light-organs, for the purpose of supplying, with a large amount of air, the tissues of this structure.

By a comparison of the main tracheal trunks and their principal branches in the abdominal segments of some of our common luminous fireflies, it was found that the arrangement of these branches was similar in each abdominal segment except the ninth, and that no new branches were added. The chief difference was found in the excessive size of the main tracheal trunks and their branches in the segments where the light-organs were located. While no new branches arose from the main tracheal trunks, those present appeared to divide much more profusely into finer and

finer branches than the corresponding trunks in the other abdominal segments, for the purpose of supplying a large amount of air to the light-organs. In the male fireflies of our most luminous species some of the longitudinal tracheal connectives in the segments containing the light-organs were not found connecting the tracheal trunks of these segments, but instead they were greatly branched supplying air directly to the light-organs.

PROCEEDINGS OF THE AMERICAN SOCIETY OF ZOÖLOGISTS

EIGHTEENTH ANNUAL MEETING

The American Society of Zoölogists held its Eighteenth Annual Meeting at the University of Chicago in conjunction with Section F. of the American Association for the Advancement of Science and in association with other biological societies, December 28, 29 and 30, 1920.

The officers for the year were:

President: Gilman A. Drew.
Vice-President: Caswell Grave.
Secretary-Treasurer: W. C. Allee.
Local Committee: H. H. Newman, Chairman, C. R. Moore and A. W. Bellamy.
Executive Committee: R. P. Bigelow, H. V. Wilson, M. M. Metcalf, George Lefevre and C. M. Child.

In the absence of the Secretary, H. V. Neal was elected Secretary *pro tem.*

BUSINESS TRANSACTED

The principal business session was held Thursday morning, December 30. The business was completed at an adjourned session held at noon of the same day.

Business from the Advisory Board

The Advisory Board authorized in 1919 and organized as follows: To serve one year, V. E. Shelford and C. C. Nutting; to serve two years, J. T. Patterson and Robert Chambers, Jr.; to serve three years, M. M. Metcalf and G. N. Calkins; to serve four years, W. E. Castle and F. R. Lillie (Chairman), recommended approval of a continuation of conferences between the Secretaries of the various Biological Societies.

The board also recommended approval of the following memorandum from the Ecological Society of America:

Report on the Preservation of Wild Life

The Ecological Society of America's committee on the preservation of natural conditions, while unable to deal with problems concerning wild life not in reserves, continually encounters the fact that individual species are menaced with extinction by agricultural encroachments. Two of these menaces are:

1. Clean-culture (roadside mowing and burning) as distinguished from roadside and streamside shrubbery and bird and original life preservation.

Birds are decreasing for lack of nesting sites, on account of destruction of breeding conditions. Entomologists and some agriculturists maintain that this condition is necessary to agriculture. Bird men insist that birds are also essential. It is known that a few states encourage roadside shrubbery while several require roadside mowing. The practice in the various parts of the United States and Canada should be ascertained. The effect of different procedures should be determined. The areas in which specially destructive and drastic measures such as burning for insect pests are necessary should be clearly defined and limited and the public informed as to the dangers of such burning.

2. Upland marshes are important as sponges storing water and letting it out slowly during dry seasons, thus controlling floods. Such marshes are gradually being drained and the flood menace is increasing every year.

The only way to save these natural resources and at the same time, the swamp faunas, especially the birds, is to utilize the swamps for agriculture. To this end several water-culture experiment stations should be established. For the present there should be one, perhaps at Cornell University, to deal with the upland marsh problems. There should be another in connection with Okefinokee swamp and one in connection with the coastal swamps of New Jersey. In addition to frogs, fish, and birds, a number of plants are good for food, etc.; e.g., cattail flour and cattail paper have recently been tried with success. Swamp potatoes, the corms of arrowhead, and seeds, roots, and stalks of our native lotus served as food for the American aborigines and pioneers. Hedrick (Science, 40: 611), Claussen (Sci. Mo., 9: 179), and Needham and Lloyd (Life of Inland Waters) have discussed these questions and suggested or advocated the improvement and culture of aquatic plants.

It is the belief of the committee that all organizations in any way interested should combine efforts for the investigation of these questions.

V. E. Shelford,
University of Illinois, Chairman.

The Society unanimously approved both recommendations.

Business from the Executive Committee

The following change in the Constitution having been approved and published as required by Article VI was unanimously passed:

Article II, add Section 4.

Foreign Zoölogists, not members of this Society, may be elected Honorary Fellows upon unanimous recommendation of the Executive Committee by a majority vote of the members present at any meeting of the Society. Honorary Fellows shall not be required to pay dues.

By-Law 5 was ordered amended to read:

It shall be the policy of the Society to hold its annual meetings in both Eastern and Central territory and the distribution of meetings between the two territories shall be determined in general on the basis of the representation of Eastern and Western members in the Society.

The Constitution and By-Laws as amended will be found on pages 233–236 of this *Journal*.

Election of Members

The Executive Committee recommended the following persons for election to membership in the Society:

1. Chapman, Royal N., B.A., M.A. (Minnesota), Ph.D. (Cornell), Assistant Professor of Animal Biology; Assistant Entomologist, *Experiment Station, University of Minnesota, Division of Entomology, University Farm, St. Paul, Minn.*
2. Dawson, James Arthur, A.B. (Dalhousie), A. M., Ph.D. (Yale), Professor of Biology, Dalhousie University, *Halifax, Nova Scotia, Canada.*
3. Dunn, Leslie Clarence, S.B. (Dartmouth), S.M., Sc.D. (Harvard), Poultry Biologist, *Connecticut Agricultural Experiment Station, Storrs, Conn.*
4. Duporte, Ernest Melville, M.Sc., B.S.A. (McGill), Instructor in Zoölogy and Entomology, Macdonald College, *Macdonald College P. O., Province Quebec, Canada.*
5. Fraser, Charles McLean, A.B., A.M. (Toronto), Ph.D. (Iowa), Professor of Zoölogy, University of British Columbia and Director of Marine Biological Station, Nanaimo, *University of B. C., Vancouver, B. C.*, or *Biological Station, Nanaimo, B. C.*
6. Goldsmith, William Marion, B.Pd., A.B., A.M., Ph.D. (Indiana), Professor of Biology, Southwestern College, *Winfield, Kansas.*
7. Grier, Norman McDowell, S. B., A.M., Ph.D. (Pittsburgh), Professor of Biology, Washington and Jefferson College, *Washington, Pa.*
8. Hecht, Selig, Ph.D. (Harvard), Assistant Professor of Physiology, *Creighton Medical College, Omaha, Neb.*
9. Hess, Walter N., A.B. (Oberlin), A.M., Ph.D. (Cornell), Professor of Biology, De Pauw University, *Greencastle, Indiana.*
10. Jewell, Minna E., A.B. (Colorado College), A.M., Ph.D. (Illinois), Assistant Professor of Zoölogy, *Milwaukee-Downer College, Milwaukee, Wisconsin.*

11. Job, Thesle T., A.B., A.M., Ph.D., Associate Professor of Anatomy, Loyola University School of Medicine, *706 S. Lincoln St., Chicago, Ill.*
12. Kudo, Rokusaburo, D.Ag.Sc. (Tokio), Instructor in Zoölogy, *University of Illinois, Urbana, Illinois.*
13. Lillie, Ralph S., A.B. (Toronto), Ph.D. (Chicago), Biologist, Nela Research Laboratories, Department of Pure Science, *Nela Research Laboratories, Nela Park, Cleveland, Ohio.*
14. Lippincott, William Adams, A.B. (Illinois College), S.B. (Iowa State), S.M., Ph.D. (Wisconsin), Professor of Poultry Husbandry and Poultry Husbandman, Kansas State Agriculture College, *Manhattan, Kansas.*
15. McCulloch, Irene, Ph.D. (California), Professor of Biology, Sophie Newcomb College, *New Orleans, La.*
16. May, Henry G., S.B. (Rochester), Ph.D. (Illinois), Professor of Bacteriology Rhode Island State College and Chief, Division of Animal Breeding and Pathology, Agr. Exp. Station, *Kingston, R. I.*
17. Muttkowski, Richard Anthony, A.B., A.M., Ph.D. (Wisconsin), Assistant Professor of Zoölogy and Entomology, University of Idaho, *Moscow, Idaho.*
18. Olmsted, J. M. D., Ph.D. (Harvard), Instructor in Physiology, Toronto University, *Toronto, Canada.*
19. Snyder, Thomas Elliott, A.B. (Columbia), M.F. (Yale), Ph.D. (George Washington), Specialist in Forest Entomology, *Bureau of Entomology, U. S. Department of Agriculture, Washington, D. C.*
20. Swingle, Wilbur Willis, A.B., A.M. (Kansas), Ph.D. (Princeton), Instructor in Biology, Sheffield Scientific School, Yale University, *Osborn Zoölogical Laboratory, New Haven, Conn.*
21. Taylor, Charles Vincent, Ph.D. (California), Assistant Professor of Zoölogy, University of California, *East Hall, University of California, Berkeley, Calif.*
22. Turner, Clarence Lester, A.B., A.M. (Ohio Wesleyan), Ph.D. (Wisconsin), Professor of Zoölogy, Beloit College, *Beloit, Wisconsin.*
23. Weese, Asa Orrin, A.B. (Minnesota), A.M. (Illinois), Professor of Biology, University of New Mexico, Secretary, Ecological Society of America, *Albuquerque, N. Mex.*

These nominees were unanimously elected.

The Journal of Morphology

The Committee on Publication appointed at St. Louis submitted the report given below to the Executive Committee. Acting by the authority given it at St. Louis, the Executive Committee approved the action of the Committee and the report gives the basis for the coöperation between the Society and The Wistar Institute in publishing the *Journal of Morphology.*

THE WISTAR INSTITUTE OF ANATOMY AND BIOLOGY
Philadelphia, Pa.

April 5th, 1920.

Dear Dr. Metcalf: In order to make perfectly clear the relation of the American Society of Zoologists to The Wistar Institute and the *Journal of Morphology*, I wish to confirm the impression that you have that the Society is to elect the Managing Editor and Associate Editors of the *Journal of Morphology*, and to make such arrangements as may seem desirable for the scientific control of this journal.

Yours very truly,

(Signed) M. J. GREENMAN.

Dr. M. M. Metcalf
Philadelphia, Pa.

To the Executive Committee of The American Society of Zoologists:

Sirs:—In accordance with your instructions, your Committee, consisting of W. E. Castle, Caswell Grave and Maynard M. Metcalf, "appointed

(1) to initiate a scientific policy concerning the *Journal of Morphology;*

(2) to nominate an Editorial Board;

(3) to consult with the Advisory Board of The Wistar Institute concerning both the proposed policy and the editorial nominations;

(4) to refer the recommendations for final action to the Executive Committee in 1920 and thereafter through the Executive Committee to the Society at its annual meeting," first consulted with each other by correspondence and in person, and afterward met with the Advisory Board of The Wistar Institute at its annual meeting, April 4th to 6th, in Philadelphia.

There was full and frank discussion at this meeting of the matters involved.

Your Committee being unanimous in its desire to nominate Prof. C. E. McClung to be Managing Editor of the *Journal of Morphology*, and having learned that such nomination would be particularly pleasing to the Director of The Wistar Institute and its Board of Advisors, obtained Prof. McClung's consent to the nomination and then asked him to meet with us in consultation upon the other items submitted to us for recommendation.

Dr. Greenman, Director of The Wistar Institute, was also further consulted in regard to all the matters mentioned in this report and there has been complete agreement of your Committee and of Prof. McClung and Dr. Greenman in the following recommendations:

I. That there be elected a Managing Editor of the *Journal of Morphology* to serve for a period of five years and that he be eligible to reelection at the expiration of his period of service.

Your Committee feels that there is no objection to long tenure of the office of Managing Editor of the *Journal* and that this is desirable.

II. That there be elected nine Associate Editors of the *Journal of Morphology*, three to serve until January 1st, 1922; three to serve until January 1st, 1923, and three to serve until January 1st, 1924.

That beginning with the annual meeting of the Society at the end of the year 1921, and annually thereafter, there be elected by the Society upon nomination by the same method as is provided for the nomination of other officers, three Associate Editors to serve for three years to take the places of the three retiring Asso-

ciate Editors. That before making nomination of such Associate Editors, the Nominating Committee shall consult the Board of Editors of the *Journal of Morphology* and also the Director of The Wistar Institute and through him the Board of Advisors of this Institute.

This is suggested as a courtesy to the Institute, not as a matter of necessity, for the final authority for the election of the Editors of this *Journal* will lie with the Society.

That a retiring Associate Editor shall not be eligible to reelection until after the expiration of one year subsequent to his retirement.

III. That the three Associate Editors elected to serve until January 1st, 1924, be constituted for the year 1921 a consulting committee to visit The Wistar Institute upon its invitation and at its expense, to familiarize themselves with the work of the Institute and to take from the Society to the Institute and receive from the Institute for the Society, suggestions as to the relations between the Society and the Institute and as to opportunities for coöperation not only in matters of publication, but in other matters as well in which the coöperation of the Institute and the Society may promote the interests of Zoölogy.

The Institute has suggested the election of such a Committee and has urged that the Society through this Committee make with freedom and frankness suggestions that may enhance the usefulness of the Society and of the Institute in their common service to Zoölogical science.

The Society should, in this connection, realize the policy of the Institute to limit for the present the field of its activity with a view to greater effectiveness through concentration of effort.

The Institute further desires from year to year, such a Consulting Committee in order that there may soon come to be in the Society a considerable number of its members who shall understand the purposes, plans and methods of operation of the Institute with a view to most effective coöperation between the two organizations.

Your present Committee recommend that this Consulting Committee be the three Associate Editors elected to serve for three years, so that they may have opportunity to enter upon their service as Editors with fuller understanding of the institution with which they will be coöperating in their editorial duties.

We further recommend that a similar Committee be appointed for the year 1922, and annually for each year thereafter and that this Committee consist annually of the three newly elected Associate Editors.

Your Committee desires to express its sense of the great value of such mutual understanding of the Society and the Institute of one another's spirit, purposes plans and methods, this sense being based upon our own informing and delightful experience as guests of the Institute for these two days.

IV. That the Board of Editors make annual report to the Society upon the *Journal of Morphology* and any matters of publication that they may wish to include.

V. That the Consulting Committee or any of its members, if they desire to do so, may report any year to the Society any suggestions or recommendations growing out of their visit to and consultations with The Wistar Institute.

VI. That Prof. C. E. McClung be elected Managing Editor of the *Journal of Morphology*.

VII. That Associate Editors of the *Journal of Morphology* be elected as follows:

1. To serve until January 1st, 1922
   Prof. Gary N. Calkins
   Prof. J. S. Kingsley
   Prof. Wm. Patton
2. To serve until January 1st, 1923
   Prof. E. G. Conklin
   Prof. M. F. Guyer
   Prof. W. M. Wheeler
3. To serve until January 1st, 1924
   Prof. C. A. Kofoid
   Prof. F. R. Lillie
   Prof. J. T. Patterson

VIII. That matters of Editorial Policy and method, not covered by the present report, be left to the Board of Editors composed of the Managing Editor and the Associate Editors, subject, of course, to any action by the Society.

It may be well to state that no fundamental changes in the character or conduct of the *Journal of Morphology* is contemplated and that it is planned to continue publishing in the *Anatomical Record* the Proceedings of the Society.

IX. That your present Committee be discharged at such time as you shall have received and have acted upon this our report.

Your Committee cannot refrain from expressing its deep sense of the generosity and the fine spirit of coöperation shown by The Wistar Institute. They are giving to our Society the unrestricted management and use of the *Journal of Morphology* which is owned by the Institute. Their only desire clearly is to increase their own efficiency and the effectiveness of the Society of Zoölogists in promoting biological research through coöperation. They not only wish to establish at once coöperation in publication, but they invite suggestion from time to time as to coöperation in other ways; the relation they suggest between the two organizations is as unique as it is generous and your Committee believes that it is another instance of statesman-like vision such as is shown in the Institute's plan, already realized, to distribute its publications more widely than any scientific serial publications have heretofore been distributed.

The only worthy thanks we can suggest from the Society to the Institute lie in accepting the proffer of coöperation and joining our efforts in effective service to zoölogical research.

We append to this report a letter from Dr. Greenman which makes clear the generous confidence of The Wistar Institute in the Society of Zoologists.

Philadelphia, Pa.
April 5th, 1920.

(Signed) W. E. Castle,
Caswell Grave,
Maynard M. Metcalf.

C. E. McClung reported to the Society concerning the present status of the *Journal of Morphology* and on motion by Dr. McClung the Society recommended that the subscription price of the *Journal of Morphology* be increased from $9.00 to $12.00 per volume.

Report of the Secretary

During the year 1920, two members of the Society have been removed by death, E. L. Michael and George D. Allen; three have resigned and six members have been dropped for non payment of dues, leaving at present, before the election of new members, 305 members of the Society.

During the year, the American Association for the Advancement of Science, recognizing the high standard of the American Society of Zoölogists in choosing their membership, agreed to recognize election to membership in the Society as a certification of eligibility to being enrolled as a Fellow in the Association. In the future, all members elected will be immediately nominated as Fellows in the Association.

The Secretary called the attention of members who enter nominations or membership that it is very important that a complete list of the nominees' publications be filed with page references and in addition that a short biographical sketch be furnished similar to that found in American Men of Science.

The report was ordered to be placed on file.

Treasurer's report for 1920.

Receipts to December 24, 1920

Balance on hand at last report		$1,204.30
68 $5.00 dues	$340.00	
201 7.00 dues	1,407.00	
17 11.50 dues	195.50	
6 irregular sums from members	23.30	
Refund from Wistar Institute	13.50	
Credit at Wistar Institute	2.00	
Interest on Savings deposits	43.69	
Uncorrected error by bank clerk	10.00	
		2,034.99
Total receipts		$3,239.29

Expenditures to December 24, 1920

To Wistar Institute for subscriptions:		
January 1	$367.00	
February 5	6.00	
July 8	1,590.00	
December 1	159.50	
Total		$2,122.50

Expenses of office of Secretary-Treasurer:			
Printing			
Tickets for Zoölogy dinner at St. Louis	$0.50		
Programs, envelopes and bills and mailing same	44.78		
Announcements	13.50		
Total for printing		$58.78	
Stenography, typewriting and office help		24.25	
Postage		19.22	
Exchange advanced on Canadian check		0.80	
Telephone and telegrams		1.75	
Express			
Programs to St. Louis	0.68		
Typewriter and records to and from Woods Hole	6.00		
Total express		6.68	
Record book for minutes of the Society		3.00	
Expenses of Secretary-Treasurer to St. Louis		41.97	
Total expenses of office of Secretary-Treasurer		$156.45	
Total expenditures			$2,278.95
Cash on hand December 24, 1920			
Savings account		$898.56	
Checking account		61.78	
Total cash on hand		$960.34	
Total cash on hand plus expenditures			$3,239.29
Bills due, payable January 1, 1921			
Wistar Institute for subscriptions	$73.50		
Correction, error of bank clerk	10.00		
Total		$83.50	
Probable balance, January 1, 1921			
Balance, December 24, 1920	$960.30		
Approximate interest on savings	13.50		
Total		$973.80	
Bills payable, January 1, 1921		83.50	
Probable balance, January 1, 1921			$890.30
Balance, January 1, 1920		$809.59	
Net gain for the year			$80.71

In addition there are 38 members in arrears for dues aggregating 61 years and amounting to $399.50, $32.50 more than last year.

The Auditing Committee, consisting of Bennet M. Allen and N. E. McIndoo, reported that they had audited the above accounts and found them correct.

The reports of the Treasurer and the Auditing Committee were received and ordered placed on file.

Election of officers

The Nominating Committee (See Art. 3, Sec. 6), composed of D. H. Tennent, Charles Zeleny and R. A. Budington, report the following nominations:

President, C. A. Kofoid.

Vice-President, A. L. Treadwell.

Member Executive Committee, to serve five years, G. A. Drew.

Member of Division of Biology and Agriculture, National Research Council, to serve three years, William Patten.

Members of the Council of A. A. A. S., C. C. Nutting, W. C. Allee.

There were no other nominations and the officers, as presented by the Nominating Committee, were duly elected.

The Executive Committee announced the appointment of C. A. Kofoid and D. H. Tennent to fill the places on the Advisory Board made vacant by the retirement of V. E. Shelford and C. C. Nutting.

Resolutions

The Society adopted the following resolutions:

Regarding duty free importation of scientific materials

The American Society of Zoologists representing the zoölogical interests of the country, especially from the standpoint of research and instruction in our American Colleges and Universities, views with much concern the proposal made in the bill H. R. 7785 which provides for an increase of 20 per cent in the duty on scientific instruments and an increase of 30 per cent on scientific glassware and in addition repeals section 573 of the tariff act of October 3, 1913, which allows for the duty free importation of such materials by educational institutions.

In view of the fact that the great mass of research in pure science is still carried on by men in our colleges and universities, an increase in the cost of scientific apparatus and equipment is especially to be deplored since even under the present arrangement of low duties and duty free import privileges, the funds at the disposal of our educational institutions are inadequate to provide for the most efficient teaching equipment or to allow for the most effective prosecution of research:

Therefore be it resolved: That the American Society of Zoologists, assembled in annual session, call the attention of Congress to the burden imposed upon the prosecution of educational and research work by the proposed repeal of the privilege of duty free importation of scientific apparatus, chemicals and glassware by educational institutions and respectfully request the continuance of this privilege in proposed tariff legislation.

The American Society of Zoölogists also requests the restoration of the privilege of the duty free importation of single copies of scientific books in the English language by members of recognized educational and scientific institutions.

That copies of these resolutions be forwarded to the Congressional Committees concerned, the National Academy of Sciences, the National Research Council and to the Executive Committee of the American Association for the Advancement of Science, and given other proper publicity as the Executive Committee of the American Society of Zoölogists shall direct.

Concerning the preservation of wild life

Whereas: The Ecological Society of America is engaged in attempting to secure the reservation of natural areas, i.e., reserves including the original flora and fauna in an undisturbed state, for research present and future. A standing committee has been listing and describing such areas reserved and desirable for reservation, during several years past. The Society is now entering on a plan to unite the various groups interested in primeval areas, namely: 1. Investigators in biology, geography, history and art. 2. Sportsmen through their interest in game sanctuaries. 3. Ornithologists through their interest in bird refuges. 4. Wild flower lovers through their interest in primeval areas as seeding centers and preserves.

The purpose of such union of effort will be to secure the preservation of natural areas in state parks, forest preserves, etc., and to secure the creation of more such parks and forest preserves.

Whereas: The number of primeval preserves, especially in the Eastern states, is wholly inadequate for either present or future research purposes and areas from which such preserves may be created are rapidly being destroyed.

Be it resolved that: The American Society of Zoölogists indorses the efforts of the Ecological Society of America to secure reserves for research purposes and directs its Secretary to forward a copy of this resolution to the Division of Biology and Agriculture of the National Research Council.

And further resolved that: The President of the Society be directed to appoint a delegate to the Parks Conference to be held in Des Moines, Iowa, January 10, 11 and 12, 1921, said delegate to represent the Society in the interest of reserves of primeval conditions for zoölogical research.

The incoming President, C. A. Kofoid, appointed V. E. Shelford to be the delegate of the Society to this conference.

Sessions for the presentation and discussion of papers

During the sessions for the presentation and discussion of papers, 54 papers were read in full, 13 of which were followed by discussion. The sessions were occupied as follows:

TUESDAY, DECEMBER 28

Room M11, Harper Library

9:00 A.M. Session for reading and discussion of papers on General Physiology.
2:00 P.M. Session for reading and discussion of papers on Embryology.

Ida Noyes Hall

8:00 P.M. Address of the retiring Vice-President of Section F. of the American Association for the Advancement of Science, W. M. Wheeler, Harvard University. *Subject:* The organization of research. The address was followed by the Biological Smoker.

WEDNESDAY, DECEMBER 29

Section A. Room M11, Harper Library

9:00 A.M. Session for reading and discussion of papers on Cytology and General Zoölogy.

Section B. Room 14, Zoölogy Building

Papers on Comparative Anatomy and Parasitology.

Section A. Room 14, Zoölogy Building

2:00 P.M. Session for reading and discussion of papers on Evolution and Genetics.

Section B. M 11, Harper Library

Joint session with the Ecological Society of America for reading and discussion of papers dealing with Ecology and Zoögeography.

THURSDAY, DECEMBER 30

Room M 11, Harper Library

9:00 A.M. Business meeting of the Society.
10:00 A.M. Symposium on Fertilization.

LIST OF TITLES

The following titles, contributed for the program, have been grouped and arranged in accordance with rules accepted by the Society.

Papers marked by an asterisk were read by title

COMPARATIVE AND GENERAL PHYSIOLOGY

1. The sensory physiology of glochidia and the mechanism of encystment. Leslie B. Arey, Northwestern University Medical School.
2. Observations of the feeding habits of oysters. (Lantern.) Thurlow C. Nelson, Rutgers College and New Jersey State Board of Shell Fisheries.
3. Responses of the de-eyed larvae of *Amblystoma tigrinum* to solid bodies. Albert Kuntz and José Zozava, St. Louis University School of Medicine.
4. The auditory sense of the honey bee. N. E. McIndoo, Bureau of Entomology, Washington, D. C.
5. The active role of oxygen in the development of fertilization eggs of rotifers. (Lantern.) David D. Whitney, University of Nebraska.
6. An experimental study of the tarsal chemoreceptors of two nymphalid butterflies. Dwight E. Minnich, University of Minnesota.
*7. The relative stimulating efficiency of continuous and intermittent light in the tachina fly, *Archytas aterrima*. William L. Dolley, Jr., Randolph-Macon College.
8. Relation of body form to spiral movement. A. A. Schaeffer, University of Tennessee.
*9. Poisonous spiders. A. M. Reese, West Virginia University.
*10. The minor pedicellariae of two species of Pacific Coast starfishes. C. O. Esterly, Occidental College.
*11. Some points concerning adaptation. W. J. Crozier, Rutgers College.
*12. Reactions to light in the larvae of the Ascidian, *Amaroucium*. S. O. Mast, The Johns Hopkins University.
13. Control of morphological polarity by means of the electric current. E. J. Lund, University of Minnesota.
14. Resistance of fish to different concentrations of salt. R. T. Young, University of North Dakota.
15. Sterilization by means of spermatoxins. M. F. Guyer, University of Wisconsin.
*16. The olfactory reactions of *Amblystoma tigrinum*. J. S. Nicholas, Yale University. (Introduced by Henry Laurens.)

EMBRYOLOGY

*17. The shrinkage of embryos in the processes preparatory to sectioning. Bradley M. Patten and Rees Philpott, Western Reserve University Medical School.
18. The experimental production of twins in the starfish, *Patiria miniata:* with a discussion of the causes of twinning in general. H. H. Newman, University of Chicago.

19. Bifurcation in the embryos of tubifex. Paul S. Welch, University of Michigan.
20. Relative sizes of pig embryos. Mary T. Harmon, Kansas State Agricultural College.
21. The effects of transplantation of the several parts of the adult hypophysis into tadpoles in *Rana pipiens*. Bennet M. Allen, University of Kansas.
22. Lipolytic effects of egg secretion. O. C. Glaser, Amherst College.
*23. Proliferation and differentiation in the central nervous system of *Amblystoma*. G. E. Coghill, Department of Anatomy, University of Kansas.
24. Sex gland transplantation and the modifying effect in rats and guinea pigs. Carl R. Moore, University of Chicago.
25. The development of connective tissue in the chick embryo. George A. Baitsell, Osborn Zoölogical Laboratory, Yale University.
26. Some habits of *Cirratulus* in relation to fertilization. John W. Scott, University of Wyoming.
*27. Homoplastic and heteroplastic endocrine transplants. W. W. Swingle, Osborn Zoölogical Laboratory, Yale University. (Introduced by R. G. Harrison.)
28. Is the initiatory effect of egg secretion specific? Alvalyn E. Woodward, Amherst College. (Introduced by O. C. Glaser.)
28a. R. A. Budington appealed for support for Professor Van der Stricht and his *Archives of Biologie* which can be given through the purchase of lantern slides made from Van der Stricht's preparations showing fertilization in *Nereis*.

CYTOLOGY

29. Cytology of *Anisolabis maritima*. (Lantern.) S. I. Kornhauser, Denison University.
30. Protoplasmic viscosity changes in the dividing egg of *Cumingia*. L. V. Heilbrunn, University of Michigan.
31. The structure and division of *Trichomonas muris* (Hartman). D. H. Wenrich, University of Pennsylvania.
*32. A comparison of a Limax Amoebae with tissue culture cells. M. J. Hogue, School of Hygiene and Public Health, Johns Hopkins University.
*33. Unusual tetrads and their bearing on the problem of crossing-over. W. R. B. Robertson, University of Kansas.
34. Spermatogenesis in Cestodes. R. T. Young, University of North Dakota.
35. Conjugation and fission-rate in *Arcella vulgaris* (Ehrenberg). Hansforth M. MacCurdy, Alma College.
*36. The occurrence of precocious and abortive maturation phenomena in female larvae of *Rana catesbiana*. W. W. Swingle, Osborn Zoölogical Laboratory, Yale University. (Introduced by R. G. Harrison.)
*37. Peculiar chromosomal phenomena in a Homopteran. Franz Schrader, Bryn Mawr College. (Introduced by L. V. Heilbrunn.)
38. The early history of the germ cells in the brook lamprey, *Entosphenus wilderi* (Gage), up to and including the period of sex differentiation. Peter Okkelberg, University of Michigan. (Introduced by Paul S. Welch.)

GENERAL ZOÖLOGY

*39. Something of the life history of a fresh water medusa. F. Payne, Indiana University.

COMPARATIVE ANATOMY

40. The history of the vertebrate mouth. H. V. Neal, Tufts College.
41. The origin of the cerebral hemispheres. C. Judson Herrick, University of Chicago.
*42. The integumental glands of *Alligator mississippiensis*. A. M. Reese, West Virginia University.
43. The order, time and rate of ossification of the vertebrate skeleton. R. M. Strong, Loyola University School of Medicine.
44. Primary neuromeres and vertebrate head segmentation. H. W. Stunkard, New York University. (Introduced by J. S. Kingsley.)
45. Studies on lymph nodes: 1. Structure, as shown by deposited ink granules. Thesle T. Job, Loyola University School of Medicine. (Introduced by R. M. Strong.)
46. The topography of the cloaca of the male *Necturus* in relation to cloacal glands. Alden B. Dawson, Loyola University School of Medicine. (Introduced by R. M. Strong.)

PARASITOLOGY

*47. Measurements of *Trypanosoma diemyctili* from different hosts and their relation to specific identification, heredity and environment. R. W. Hegner, School of Hygiene and Public Health, Johns Hopkins University.
48. Notes on the development and distribution of *Oncicola canis* (Kaup 1919). H. J. Van Cleave, University of Illinois.
49. *Dermatobia hominis*. Thomas Byrd Magath, Mayo Clinic.
*50. The development of the Japanese blood-fluke, *Schistosoma japonicum* Katsurada, in its final host. W. W. Cort, School of Hygiene and Public Health, Johns Hopkins University.
51. The course of migration of *Ascaris* larvae from the intestine to the lungs. B. H. Ransom and Eloise B. Cram, U. S. Bureau of Animal Industry.
*52. Life history of a new Limax Amoeba. M. J. Hogue, School of Hygiene and Public Health, Johns Hopkins University.
53. Correlation of the life-cycle of a parasite with the metamorphosis of its host. Nadine Nowlin, University of Kansas.
*54. Observations on the occurrence and life history of *Cephalobium microbivorum* (Cobb). James E. Ackert, Kansas State Agricultural College.
55. Studies on the sheep stomach worm, *Haemonchus contortus*. John E. Guberlet, Oklahoma Agricultural Experiment Station.
56. Acanthocephala from the American eel. H. J. Van Cleave, University of Illinois.

EVOLUTION AND GENETICS

57. The production of mosaic males from fertilized eggs in Hymenoptera. P. W. Whiting, St. Stephen's College.

58. The direction and frequency of mutation in a series of multiple allelomorphs. Charles Zeleny, University of Illinois.
59. On the relation of stale sperm to fertility and sex in ring-doves. Oscar Riddle and Ellinor H. Behre, Department of Experimental Evolution, Carnegie Institution of Washington.
60. Genetic analysis of low crossover stock produced by selection. J. A. Detlefsen, College of Agriculture, University of Illinois.
61. A note on the inheritance of polydactylism in cattle. E. Roberts, College of Agriculture, University of Illinois.
62. Selection in Cladocera. (Lantern.) Arthur M. Banta, Station for Experimental Evolution.
63. A study of the character and mode of origin of eighteen mutations in the X-chromosome of *Drosophila*. H. J. Muller, University of Texas, and E. Altenburg, Rice Institute.
64. Further studies on inheritance of color in the turkey. W. R. B. Robertson, University of Kansas.
65. Experiments with typhoid agglutinins in rabbits. M. F. Guyer and E. A. Smith, University of Wisconsin.
66. Flat-fish with unusual pigmented areas. (Lantern.) Arthur M. Banta, Station for Experimental Evolution.
67. A new type of sex-linked lethal in Drosophila. David H. Thompson, University of Illinois. (Introduced by Charles Zeleny.)
*68. The course of evolution in the king snakes. Frank N. Blanchard, University of Michigan. (Introduced by Paul S. Welch.)

Joint meeting with Ecological Society of America

ECOLOGY AND ZOOGEOGRAPHY

Contributed by members of both Societies except as noted

These papers were read at a joint session with the Ecological Society of America. Unless otherwise noted, papers are by members of both Societies.

69. The circulation of water in the Bay of Fundy, and its bearing on the distribution of the fauna. James W. Mavor, Union College.
70. The geographical distribution of the Anura and their Opalinid parasites. M. M. Metcalf. (A. S. Z.)
71. Distribution of fishes in Wisconsin lakes. A. S. Pearse, University of Wisconsin.
72. Data on the distribution of fresh-sponges in North America. Frank Smith, University of Illinois.
73. Quantitative and chemical studies of the plankton of Lake Mendota. (Lantern.) C. Juday, Wisconsin Geological and Natural History Survey.
74. Hydrogen ion concentration of natural waters and the importance of its measurement. (Lantern.) V. E. Shelford, University of Illinois and Illinois Natural History Survey.
75. An analysis of the spawning habits of Chaetopleura apiculata. B. H. Grave, Wabash College. (A. S. Z.)
76. South America and its intercontinental land connections as indicated by a survey of the geographical distribution of the Anura and their Opalinid parasites. M. M. Metcalf. (A. S. Z.)

77. Relation of temperature and tides to the quantity and distribution of oyster larvae. (Lantern.) E. P. Churchill, University of South Dakota.
78. Some reactions of the jelly-fish, Aequorea. A. O. Weese and M. T. Townsend. (E. S. A.)
79. Longevity of the Trogoderma tarsale larvae without food. J. E. Wodsedalek, University of Idaho.
80. The problem of the local distribution of Thiasiapillus imbricatus (Lamarck). Harold S. Colton, University of Pennsylvania.

SYMPOSIUM ON FERTILIZATION

81. Some phases in the evolution of sexual reproduction in the Protozoa. (30 minutes.) C. A. Kofoid, University of California.
82. The initial event in fertilization. (20 minutes.) F. R. Lillie, University of Chicago.
83. The susceptibility of the inseminated egg to hypotonic sea-water; A contribution to the analysis of the fertilization reaction. (20 minutes.) E. E. Just, Howard University.
84. Fertilization and egg secretions. (20 minutes.) O. C. Glaser, Amherst College.
*85. Chromosomes and fertilization. (20 minutes.) C. E. McClung, University of Pennsylvania.
86. Chromatic material in hybridization. (20 minutes.) D. H. Tennent, Bryn Mawr College.

Papers received too late to be listed on the regular program.

†87. Allelomorphism in Bruchus. J. K. Breitenbecher, University of Oklahoma. (Introduced by A. Richards.)
†88. A new method of ingestion exemplified in the Ciliate, Frontonia. William M. Goldsmith, Southwestern College. (Introduced by S. O. Mast.)
†89. Copper: Its occurrence and rôle in insects and other animals. Richard A. Muttkowski, University of Idaho. (Introduced by J. E. Wodsedalek.)
90. The postembryonic development of the compound eye of Drosophila melanogaster. Joseph Krafka, Jr., University of Georgia. (Introduced by Charles Zeleny.)
91. The sex element in the flash of the firefly. C. R. Fountain, Mercer University. (Introduced by R. A. Budington.)

Nos. 90 and 91 were called and read by special vote of the Society.

EXHIBITS

Room 24, Zoology Building

1. A larva of Dermatobia hominis. Thomas Byrd Magath, Mayo Clinic.
2. Dove embryo "monsters" and abnormalities obtained by altered pressures of oxygen. Oscar Riddle, Station for Experimental Evolution.
3. A small, continuous acting centrifuge for the recovery of minute aquatic organisms. C. Juday, Wisconsin Geological and Natural History Survey.
4. Rabbits showing inherited eye-defects induced by fowl serum sensitized against the crystalline lens of the rabbit. M. F. Guyer and E. A. Smith, University of Wisconsin.

†Not called.

5. Specimens of Trogoderma tarsale larvae undergoing starvation. J. E. Wodsedalek, University of Idaho.
6. Twelve quarto, colored plates of a monograph on the Dinoflagellata. C. A. Kofoid, University of California.
7. A series of 2-mm. human embryos. George W. Bartelmez, University of Chicago.
8. Quadruplets in Armadilli. H. H. Newman, University of Chicago.
9. Apparatus for measuring light intensity. V. E. Shelford, University of Illinois.
10. Breeding experiments with tropical fish. A. W. Bellamy, University of Chicago.

ABSTRACTS

COMPARATIVE AND GENERAL PHYSIOLOGY

1. The sensory physiology of glochidia and the mechanism of encystment. LESLIE B. AREY, Northwestern University Medical School.

Fresh water mussels pass through a larval stage known as the glochidium. Metamorphosis is contingent upon a temporary ectoparasitic existence upon the gills, or other soft parts, of appropriate fish-hosts. In this investigation the range of sensory-motor activities of the minute, bivalved glochidia has been tested, especially for the purpose of ascertaining the nature of the stimuli which lead to their attachment on the host and induce the latter to initiate cyst proliferation.

There are two great groups of glochidia: some species possess valves equipped with hooks; the majority, however, are hookless. It is the existing belief that hooked glochidia attach to hosts because of a closure of the valves resulting from a tactile, or contact stimulus; hookless forms, on the contrary, are denied a delicate tactile sensibility, and, it is said, the effective stimulus is a chemical one, derived from exuding blood.

Detailed experimentation proves not only that glochidia of both types respond actively to touch, the receptive organs being the hair cells of the mantle, but that this tactile response is entirely adequate to insure attachment. Although glochidia react to a wide range of chemical agents, and to some in great dilution, chemical excitation through minute gill haemorrhages, or otherwise, is not responsible for the usual attachment of either hooked or hookless glochidia to fishes. An interpretation based upon mechanical contact satisfied the facts, and this tactile responsiveness is adequate to produce the infections obtained both experimentally and in nature.

The formation of a cyst about an attached glochidium is likewise basicly a mechanical response—the overgrowth of an abrading foreign body by host tissue. Experiment indicates that the glochidium itself does not induce the response through chemical stimulation; moreover, encystment has been successfully imitated by affixing to excised gill filaments minute metallic clips, the size of glochidia or smaller. There is, however, a superimposed regulatory factor which normally prevents the formation of too bulky a cyst; this influence is lost to a filament after its excision.

2. Observations of the feeding habits of oysters. (*Lantern.*) THURLOW C. NELSON, Rutgers College and New Jersey State Board of Shellfisheries.

The present paper is a preliminary report on series of studies of food and feeding of oysters, begun in March, 1919, at floating laboratory

for oyster investigations of New Jersey Experiment Station, at Little Egg Harbor, New Jersey. Experiments carried on in open waters with oysters on bottom surrounded by natural conditions. Recording apparatus above the surface registered all movements of oyster shells, and at each complete opening or closure, samples of water surrounding the oyster were tested for density, temperature, turbidity, and food content.

Results of experiments show: Average of 20 hours activity per day. Sixty per cent of hours of inactivity during night. Seventy-four per cent of closures took place during ebb and low tide, of which only twelve per cent due to lowering of density below normal limits of toleration. Sixty-three per cent of openings occurred during flood and high tide. Oysters accustomed to density fluctuations from 1014 to 1018 did not open to feed in water below 1008. Feeding continued in waters bearing as high as 0.2 gm., dry weight, of suspended matter per litre. Mud and discarded slime strings ejected at frequent intervals by sudden partial closure of shell, contractions of adductor muscle becoming at times almost rhythmical. No correlation found between feeding periods and abundance of food. Oysters found to vary rate of filtration independent of temperature. Stereoptican illustrations show apparatus used and curves made by oysters during feeding.

3. Responses of the de-eyed larvae of Amblystoma tigrinum to solid bodies. Albert Kuntz and José Zozaya, St. Louis University School of Medicine.

De-eyed larvae of Amblystoma tigrinum respond in a characteristic manner to a solid body which approaches the head or lateral surface of the anterior portion of the trunk in the water although actual contact does not occur. This response is probably the result of stimuli received by receptors in the integument.

4. The auditory sense of the honeybee. N. E. McIndoo, Bureau of Entomology, Washington, D. C.

Beekeepers are agreed that bees can hear, yet they cannot prove it and critics still contend that it has never been experimentally proven that any insect can hear; nevertheless, within the last few years some good experimental results have been obtained.

The special sound-producing apparatus of the honeybee consists of the membranes lying between the axillaries at the bases of the front wings. Muscles, lying in the thorax and attached to these axillaries, contact and relax very quickly, thereby causing the axillaries to vibrate; consequently the above membranes are caused to vibrate rapidly, thus producing the piping, teeting, or squealing noise, commonly heard when a bee is squeezed.

Up-to-date five so-called auditory organs have been found. Judging from their anatomy, the pore plates, Forel flasks, pit pegs and Johnson's organ, all located in the antennae, do not seem to be well fitted to act as sound receptors; but the chordotonal organs, lying in

the tibiae seem to be better adapted for this purpose. The Johnson's organ consists of the peculiarly modified articular membrane between the second and third antennal segments and of many sense cells whose fibers unite with peculiar knobs extending inwardly from the articular membrane. The chordotonal organs are quite complicated, resembling those in certain Orthoptera.

The sound-producing apparatus and Johnson's organ in the honeybee, and also a minor detail in the histology of the pore plates, are here described for the first time.

5. The active rôle of oxygen in the development of fertilization eggs of rotifers. (*Lantern.*) DAVID D. WHITNEY, University of Nebraska.

The fertilized eggs of the rotifer, Brachionus bakeri, have thinner surrounding envelopes than many other species of rotifers. If freshly produced eggs are placed in water through which a stream of air is passing nearly all of them will segment. At the end of 52 hours over 90 per cent of them will contain embryos ranging from the 2 cell stage to the young that are ready to emerge. Very few of these eggs hatch because the envelopes are so firm and tenacious that the young are unable to break through them. If these eggs are not aerated they do not develop.

It was found that if these newly-laid fertilized eggs were sealed up in vials together with large numbers of micro-organisms and the whole mass allowed to decompose 3–8 days, they would immediately begin to develop when aerated. The young would develop and break out of the egg membranes in less than 18 hours.

The decomposition of the organic matter effects the egg membranes in such a manner that they not only are more permeable to oxygen but also are readily broken open by the young rotifer when it is ready to emerge.

6. An experimental study of the tarsal chemoreceptors of two nymphalid butterflies. DWIGHT E. MINNICH, University of Minnesota.

The nymphalid butterflies, Pyrameis atalanta Linn. and Vanessa antiopa Linn., respond to chemical stimulation by uncoiling the proboscis. By means of this response, it has been possible to locate and to study some hitherto unknown organs of chemical sense in these butterflies. These organs are located in the tarsi of the four walking legs, and, while their exact distribution has not been determined, experiments show that they are present at least in that portion of the tarsus comprising the distal end of the proximal segment and the four distal segments. The organs in question are contact chemoreceptors, that is, they are stimulated through intimate contact with the source of stimulating material.

In both Pyrameis and Vanessa, the tarsal chemoreceptors distinguish applejuice, which is one of the natural foods of these animals, from distilled water, although the organs are sensitive to both substances. Additional experiments on Pyrameis showed that it is also able to dis-

tinguish a 1M saccharose solution from distilled water, and such solutions as 1M HCl, M 600 quinine sulphate, and 1M NaCl from either distilled water or 1M saccharose. One very important function of the tarsal chemoreceptors, therefore, appears to be in connection with food substances and water. Not only are the animals enabled to detect the presence and exact location of such substances in the substrate, but they are also able to make some discrimination as to their nature.

7. *The relative stimulating efficiency of continuous and intermittent light in the tachina fly, Archytas aterrima.* WILLIAM L. DOLLEY, JR., Randolph-Macon College, Ashland, Va.

Ten photopositive flies were tested in intermittent light of an illumination of 35 m.c. at the following flash-frequencies, 2, 5, 10, 20, 30, 40, and 50 per second. Six insects were each tested in the same flash-frequencies as above in the following illuminations, 3 m.c. and 100 m.c. In an illumination of 35 m.c. intermittent light of certain flash-frequencies has a greater stimulating effect than continuous light of equal illumination, the maximum being at a flash-frequency of approximately 15 per second. As the flash-frequency is raised above 15 per second the stimulating efficiency of intermittent light decreases until it becomes equal to that of continuous light at slightly over 50 per second. As the flash-frequency is lowered below 15 per second the stimulating efficiency of intermittent light decreases until it becomes equal to that of continuous light at about 5 per second and less than that of continuous light at 2 per second. In an illumination of 100 m.c. the maximum stimulating efficiency of intermittent light is at a flash-frequency of approximately 20 per second, while in 3 m.c. it is at a flash-frequency of between 5 and 15 per second.

The results of these experiments consequently are in harmony with those previously reported for Vanessa antiopa in showing that the stimulating efficiency of intermittent light depends upon the flash-frequency, i.e., it may be greater, equal to, or less than that of continuous light. They also indicate that the flash-frequency at which intermittent light has a maximum stimulating efficiency varies with the illumination.

8. *Relation of body form to spiral movement.* A. A. SCHAEFFER, University of Tennessee.

The discovery that, as far as known, all motile organisms move in some form of spiral path when the orienting senses are not functioning has raised the question whether there is any relation between the shape and position of the body and the form of the path. Considered as a problem in engineering it is found that some one-celled organisms with spiral shaped bodies swim in a spiral path that conforms with the form of the body while in others the spiral path turns in a direction that is the opposite of that of the form of the body; the former swim along the path of least resistance, the latter against it. Again the position of the body, that is, whether the long axis is perpendicular to or in the plane of the

surface on which the organism moves, does not materially influence the spirality of the path. The only organism readily fulfilling these conditions is man. Numerous records of men and women while swimming under experimental conditions show definite spiral paths which are similar in general to the paths made by persons while walking.

9. Poisonous Spiders. A. M. Reese, West Virginia University.

For many years there has been a difference of opinion in regard to the poisonous characteristics of spiders, especially in regard to the so-called "black" or "black widow" spider, *Latrodectes mactans.*

Comstock and other authorities, in spite of numerous apparently authentic cases that have been reported, have maintained that this spider is at least not deadly, and is possibly not even dangerous to man.

In 1915 V. L. Kellogg reported a case in which a man in California was dangerously affected by the bite of a spider that was caught and identified as *L. mactans.*

The most recent case that has come to the attention of the writer, reported to him by the sister of the victim and by one of the attending physicians, was a Mr. L— of Oklahoma, a strong, healthy man of thirty-eight years. As in nearly all of the cases previously reported, he was bitten on the penis while using an outcloset. The resulting symptoms were as in other similar cases; violent, spasmotic pains that refused to yield to ordinary narcotic treatment; restlessness, etc. He died about thirty-two hours after being bitten, in spite of the efforts of three physicians.

10. The minor pedicellariae of two species of Pacific Coast starfishes. C. O. Esterly, Occidental College.

In addition to pedicellariae of the type well known as crossed minor, the starfishes Pisaster capitatus and P. ochraceus have two kinds of small pedicellariae, not yet described, in which the jaws do not cross. The straight form called "elbows" are found along with the crossed minors around the bases of the spines on the aboral surface. The other small straight pedicellariae are located almost exclusively at the bases of the gill filaments and for that reason are called papular.

The three sorts of minor pedicellariae differ in behavior as well as in structure. The activities of the crossed minors in Pisaster are similar to those described for Orthasterias (Asterias) forreri by Jennings. The elbows remain closed under varied conditions. They do not open even when the animal is fairly bristling, with the crossed minors standing up beyond the ends of the spines and the jaws gaping widely. If the elbows are touched they sink down into the soft flesh until invisible, and if the integument or a tuft of gills is stroked with a bristle the elbows nearby disappear. Occasionally an elbow pedicellaria opens without any apparent cause, and it remains open if touched or if the flesh or a tuft of gills is tapped lightly with a bristle or small glass rod. It is very unusual, however, to find any of the elbows open.

The papular pedicellariae can be observed when the gills are expanded well. When the animal is undisturbed most of the jaws are

nearly closed but one here and there will open and close slowly. One pedicellaria alone will open if the outside of the jaw is touched but many on a tuft of gills open when the surrounding flesh is tapped or when the ends of the gill filaments are lightly swept. An open pair of jaws snaps shut if touched on the inside, but not if the point stimulated is on the outside of one of the jaws. A pedicellaria swings around and over toward a point near it that is touched and opens during the movement or after it is completed.

The crossed minors are known to be most efficient organs, but the actual usefulness of the elbow and papular pedicellariae may be questioned. The functions of both the latter are problematical.

11. Some points concerning adaptation. W. J. Crozier, Rutgers College.

1. *Oxyhaemoglobin in Ascaris.* The observations of several writers is confirmed that oxyhaemoglobin is present in the tissue spaces of A. lumbricoides, commonly regarded as an anerobic organism. There is some reason for the opinion oxygen carried in this way may be important for fertilization of the eggs and for their earliest development. The alkalinity of the body juice of Ascaris is about equal to that of other animals, pH 7.6.

2. *On the growth of the fins in teleosts.* In Epinephelus various linear dimensions of the body, including the radial lengths of the several fins, are directly proportional to the length of the individual. The *area* of each of the fins is proportional to the square of the body length. Each fin consequently grows, during post larval life, at a constant rate. The different sizes of the several fins, as related to their separate functions, must therefore be due to some property of the organization of the animal as a whole, resulting in the establishment of differently sized primordia previous to the onset of the constant growth-rate—and not to adaptive differential deviations from this fundamental rule of growth in fishes during post-larval life.

3. *The periodic swarming of Odontosyllis enopla.* The hour of swarming of this luminous annelid, following a lunar periodicity, changes during the successive months of the breeding season (May to November), in such a manner as to be nicely adjusted throughout to the time of nightfall and of moonrise.

4. *Persisting rhythm of light-production in balanoglossids.* Ptychodera and Glossobalanus may maintain for some eight days a clear-cut diurnal rhythm of light-production while remaining continually in the dark. The reciprocal experiment could not be made, for even at night the expulsion of luminous materials is promptly inhibited by illumination.

5. *Multiplication by fission in a balanoglossid.* Ptychodera was in some species shown by Willey to occur in two forms, differing in the length of the gill series. These forms are demonstrated to result from the general occurrence of the habit of autotomous division, a normal method of multiplication in this species, especially during summer months.

6. *Photic sensitivity of the skin of Ogilbia.* O. verrellii Garman, found under stones in the shore zone at Bermuda, is nearly related to certain blind fishes of Cuban caves. According to Eigenmann, these cave fishes probably exhibit integumentary photosensitivity. O. verrillii is remarkably sensitive to light (negatively phototropic), although its eyes are quite small, and its skin is photosensitive—the second case of its kind known among many tested marine genera. This condition is of prime importance for the understanding of the preadaptation of the eyeless cave fishes in this respect.

12. Reactions to light in the larvae of the Ascidian, Amaroucium. S. O. Mast, The Johns Hopkins University.

The larvae of Amaroucium are much like a tadpole in shape but they have only one eye and this is located at the posterior end of the body near the base of the tail.

When they emerge from the colonies they are strongly photo-positive, after a few moments they become photo-negative and remain so until they become attached and begin to metamorphose.

If the light is rapidly reduced resting specimens, both positive and negative, respond by becoming active and active specimens respond by changing their direction of locomotion, the positive specimens turning toward the abeye and the negative ones toward the eye-side.

Increase in illumination has no effect on resting specimens regardless as to how rapid or extensive it may be but active specimens respond by changing the direction of motion. This was ascertained with certainty only in negative specimens. These turn toward the abeye-side.

The reaction time is so short that if the hand is moved up and down in front of the microscope as rapidly as possible, alternately increasing and decreasing the luminous intensity, the tail in attached specimens swings from side to side in harmony with the movement of the hand.

If the illumination is gradually changed in either direction there is no response regardless as to how extensive the change may be. The responses to light are dependent upon the time-rate of change in illumination. They are in this respect like the responses in Euglena known as 'shock-reactions' 'schreckbewegung.'

The eye functions as a photo-receptor. If the larvae are attached and a compact source of light is moved in such a way as to produce changes in the illumination of the retina without any change in the illumination of the field responses are induced which are precisely the same as those induced by changing the illumination in the field.

Orientation is brought about by responses (shock-reactions) induced by rapid changes in the illumination of the retina owing to the rotation of the organism on the longitudinal axis resulting in alternate exposure and shading. In negative specimens shading causes the tail to bend toward the eye, exposure toward the abeye-side; in positive specimens precisely the opposite. The one set of responses directs the organism from, the other towards the source of the light. After the tadpoles

are oriented the retina is continuously approximately equally illuminated, the shock reactions cease, and the animals continue on the course established. They remain oriented not because they are held on their course by continuous stimulation, as is so frequently maintained, but because they tend to continue on a direct course when they are not stimulated.

Orientation in this organism is in no way dependent upon a balanced effect of stimuli acting continuously on symmetrically located photoreceptors in accord with the DeCandolle-Verworn theory of orientation accepted by Loeb.

13. Control of morphological polarity by means of the electric current. (Lantern.) E. J. Lund, University of Minnesota.

In 1917 the writer called attention to the similarity between undifferentiated heteropolar individuals of Bursaria, and the ciliary beat in e.g. Paramecium subjected to the electric current. If these phenomena have anything in common then it should be possible to influence the process of establishment of morphological polarity by subjecting differentiating tissues or cells to a direct electric current. This has proven to be the case in internodes cut from Obelia and subjected to a current of proper density. Some of the important facts are:—

A. Regeneration without current. 1. Polyp formation at apical end of an internode occurs before polyp formation at basal end. 2. Apical internodes develop polyps earlier than internodes of basal origin.

B. Regeneration in current. 1. With appropriate current density all polyp formation toward cathode (−) can be delayed if not entirely inhibited, while at the same time polpys may form on anode (+) end in a high percentage of pieces. 2. Under conditions in 1, stolons form and function normally on end toward cathode. 3. Statements 1 and 2 hold for pieces irrespectively of whether basal or apical end is pointed toward anode. 4. A current density barely able to inhibit regeneration in basal internodes can not inhibit regeneration in apical internodes of same branch.

The writer believes that he has succeeded in reversing the original polarity and in determining completely the polarity of regenerating Obelia internodes with an electric current. The establishment of an electrical polarity is probably a fundamental associated condition for development of morphological polarity. The probable relation of the above facts to the earlier discovery of axial differences of electrical potential in uninjured plants and animals by Burdon-Sanderson, Mathews, and others, is apparent.

14. Resistance of fish to different concentrations of salt. R. T. Young, University of North Dakota.

Experiments conducted with several species of fish at the North Dakota Biological Station at Devils Lake indicate that the lake has about reached that degree of concentration (16,000 p. p. m.) which fish can withstand. The sulphates of magnesium and sodium, and chlorides

of sodium, calcium and potassium and sodium carbonate have been used as experimental salts. Osmotic pressure appears to be the main factor in limiting the life of the fish, but a specific toxic effect is also evident.

15. Sterilization by means of spermatoxins. M. F. GUYER, University of Wisconsin.

The action of spermatoxins in vitro has been known since 1899. My problem was to determine how they act in vivo. Spermatoxic serum was prepared by injecting fowls repeatedly with the spermatozoa of rabbits. When, through observation of its effects on spermatozoa in vitro, such serum was found to have become effective it was introduced into the blood stream of four male rabbits at intervals of two or three days until each rabbit had received five or six injections. One rabbit died. One became wholly sterile and the other two partially so. Sterility was determined both by breeding tests and by examination of the semen for spermatozoa. The first rabbit was still sterile, by the breeding test, seven months later when killed for microscopical examination of the testis. The other two still exhibit fertility though it has apparently not been fully restored.

Fowl-serum sensitized against rabbit spermatozoa is also toxic, in vitro, for the spermatozoa of guinea pigs though less so than for those of rabbits.

16. The olfactory reactions of amblystoma tigrinum. J. S. NICHOLAS (Introduced by Henry Laurens), Osborn Zoological Laboratory, Yale University.

General observations upon the behavior and growth of operated larvae (noseless, eyeless and both noseless and eyeless) show that food or test substances are obtained principally by the sense of sight. Under conditions in which motionless food substances alone are present, the olfactory apparatus functions more effectively in the eyeless than in the normal(seeing) larvae.

Experiments performed with adult animals also show that while the eye is the most important agent in locating food materials yet the nose is capable of detecting and localizing a diffusing food substance.

Tests made with the animals in darkness show a distinct retardation in reaction time when compared with that of the blinded animals. This difference is attributed to dependance upon the sense of sight in the normal animal while in the blinded animal a correlation, by which the olfactory sense is rendered more efficient has been effected.

Experiments performed with diffusing and non-diffusing substances demonstrate the fact that animals possessing olfactory sense (blinded) are stimulated by diffusing substances while those which possess the sense of sight (nose-stopped) are stimulated by non-diffusing substances, particularly if these are in motion.

Air-borne odor streams are effective only when substances possessing irritating properties are used.

The experiments indicate clearly that there is a definite olfactory sense in the larvae and adults of A. tigrinum.

EMBRYOLOGY

17. The shrinkage of embryos in the process preparatory to sectioning. Bradley M. Patten and Rees Philpotte. Western Reserve University School of Medicine.

To ascertain the amount of shrinkage which is induced by preserving embryological material and preparing it for sectioning, series of measurements were made on pig embryos covering each stage of some of the common technique.

The fixatives used were: Zenker, Orth, Tellyesnicky, 10 per cent formalin, formol-alcohol, and Bouin. The crown-rump length of the embryos was measured first in the amniotic fluid, and thereafter following each solution with which they were treated. The average shrinkage was computed in per cent of the original length of the embryo. From these averages graphs were plotted to show the shrinkage encountered at each step of each of the techniques used.

The shrinkage in the bichromate fixatives, Zenker, Orth, and Tellyesnicky, was the greatest encountered, the decrease in crown-rump length ranging from about 30 per cent in 10 mm. embryos to about 20 per cent in 20–25 mm. embryos. The greater shrinkage in the younger embryos is probably attributable to the less compact condition of their mesoderm. Most of the shrinkage in these techniques came in the fixatives themselves.

Fixation in 10 per cent formalin and in formol-alcohol resulted in an initial swelling which was followed by rapid shrinkage during dehydration. The total shrinkage of formalin-fixed material after paraffin infiltration approximated that encountered in material fixed in the bichromate solutions.

The shrinkage in Bouin's fluid was slight but continued during dehydration and infiltration. The total shrinkage in the process was somewhat less than that in the bichromate fixatives.

Comparison of the several graphs shows a tendency for shrinkage in dehydration and paraffin infiltration to be greater following those fixatives which cause less initial shrinkage. This practically nullifies, as far as material for paraffin sectioning is concerned, the supposed advantages of solutions compounded to avoid shrinkage in the fixative.

18. The experimental production of twins in the starfish Patiria miniata: with a discussion of the causes of twinning in general. H. H. Neuman, University of Chicago.

A series of separate twins and of double monsters were produced under three different experimental conditions: *a*) as the result of an extremely belated parthenogenetic development; *b*) as the result of fertilizing Patiria eggs with the sperm of another species of starfish; *c*) as the result of overcrowding normally fertilized eggs. All three methods involve retardation of development, with loss of precise axiate organization at some critical period. Redifferentiation or resumption of axiate organization occurs, but unity of organization has been lost, so that two or more axes or gradients appear instead of the original one. Thus twins or double structures arise.

A series of twin types are produced which represent the results of differences in the earliness of onset of retardation and more or less complete recovery. The series includes completely separated half-sized and quarter-sized blastulae and gastrulae, full-sized gastrulae with two or more archentera, larvae in which the archenteron branches anteriorly into "dicephalous" larvae, and advanced bipennariae with paired, instead of only left-hand, madreporic pores and pore-canals. This physiological theory of twinning agrees with the writer's formerly expressed theory to explain the cause of specific polyembryony in the armadillo.

19. Bifurcation in the embryos of tubifex. Paul S. Welch, University of Michigan.

Embryonic development in *Tubifex tubifex* (Oligochaeta) has been found to exhibit a striking frequency of abnormalities, chief among which are various forms of body bifurcation. In a series of over 500 cocoons secured from natural habitats and laboratory cultures approximately 20 per cent yielded duplicities. Many types and combinations of type occur, the principal ones being 1) anterior, posterior, or both; 2) simple or compound; 3) equal or unequal; and 4) sagittal, frontal, or both. Anterior doubling appeared about twice as frequently as posterior doubling, and the two types combined in the same individual occurred almost as frequently as the former. Compound bifurcations were not uncommon. Depth of division at the anterior region varied from 1 to 6 somites; in the posterior region from 1 to 17 somites. Bifidity constitutes an almost complete barrier to escape from the cocoon. Careful examination of more than four thousand newly emerged worms yielded only 10 bifid individuals. These anomalies may live within the cocoon long after their escape from the egg membrane, the maximum record being 98 days. Attempts to rear such individuals in laboratory cultures favorable for normal worms of similar age have thus far been unsuccessful and examinations of thousands of both mature and immature worms taken from native habitats and long continued laboratory cultures have failed to reveal a single duplicity. Morphological peculiarities involving the principal internal systems accompany these abnormalities of body form and are given special consideration.

20. Relative sizes of pig embryos. Mary T. Harmon, Kansas State Agricultural College.

The examination of forty-five pregnant pig uteri containing three hundred eleven embryos ranging in length from 18 mm. to 240 mm. and in weight from 0.48 gm. to 872 gm., sixteen litters of pigs born at term consisting of one hundred fifty-nine pigs ranging in weight from 11 oz. to 3 lbs. 10 oz., and three uteri containing embryos of known duration of pregnancy has led to the following conclusions:

1. That there is a great variation in the length and weight of the embryos within a single pig uterus. 2. That this variation is similar

in the early stages of pregnancy as well as the later stages of pregnancy. 3. That this variation is similar in uteri containing few as well as many embryos. 4. That it is also similar in uteri containing the same number of embryos in each horn as those containing more embryos in one horn than in the other. 5. That the variation in length is independent of the variation in weight and vice versa. 6. That the position of the embryo within the horn is not correlated with the variation either in length or weight. 7. That abnormalities are not necessarily correlated with the degree nor direction of the variation either in length or weight. 8. That runts are not more common than unusually large embryos. 9. That the regularity of the distribution of the variation indicates that it may be due to segregation. 10. That the presence of more embryos in one horn of a uterus is a very small factor, if indeed a factor at all, in producing these variations. 11. That the data from the sixteen litters of pigs born at term and those from the three uteri of known duration of pregnancy is in perfect accord with those data obtained from the uteri secured at the packing house. 12. That distribution of the sizes of the pigs born at term strongly indicates segregation in variation in weight. 13. That the age of the mother and the breed of the pigs may affect the limits of size, but not the variation within these limits. 14. That there was one small embryo which may be a case of superfetation and one which may be a case of death in utero and resorption.

21. The effects of transplantation of the several parts of the adult hypophysis into tadpoles in Rana pipiens. BENNET M. ALLEN, University of Kansas.

Microscopic examination of specimens preserved at from two to five months after the operation show that the transplant has lived in normal and apparently functional condition in three-fourths of the specimens studied. This is evidenced not only by their structure but by their vascularization as well.

1. Anterior lobe of the hypophysis transplanted: *a*, Into *normal* tadpoles causes acceleration of development. *b*. Into *pituitaryless* tadpoles induces tendency toward metamorphosis that falls just short of the breaking through of the fore limbs. The thyroid glands show a proportional development, being much larger and containing more colloid than they otherwise show in pituitaryless tadpoles. *c*. Into *thyroidless* tadpoles fails to produce any appreciable tendency toward metamorphosis. Examination of 6 more or less completely metamorphosed specimens in this lot showed in each instance a well developed piece of thyroid gland accidentally left behind in the operation.

These experiments clearly show that the anterior lobe of the hypophysis exerts an influence upon metamorphosis only indirectly through its influence upon the thyroid gland. The anterior lobe stimulates growth especially during early stages; but in these experiments this did not amount to gigantism.

2. Transplantation of the united intermediate and posterior lobes into pituitaryless tadpoles causes them to revert to the original black color after having become white as a result of prior pituitary extirpation. This is due to the action of the intermediate lobe alone as other experiments show. Many such operated tadpoles took on a grey color after several weeks owing to the degeneration of the implanted tissue. Transplantation of the intermediate lobe does not stimulate the development of the thyroid gland; for this reason it likewise has no effect upon metamorphosis.

It seems highly probable that parts of the hypophysis other than the anterior lobe are essential to complete metamorphosis. It is very probable that the pars tuberalis plays a role.

22. Lipolytic effects of egg secretion. O. C. Glaser, Amherst College.

This is a study of hydrolysis in neutral fats and ethyl butyrate under the influence of secretions from arbacia eggs. Definite proof is brought forward showing that hydrolysis is accelerated and that egg secretions contain one or more lipolytic enzymes capable of isolation. An attempt is made to correlate these results with the findings of others and with current theories of fertilization.

23. Proliferation and differentiation in the central nervous system of Amblystoma. G. E. Coghill, Department of Anatomy, University of Kansas.

There is no suggestion of metamerism in either proliferation or differentiation.

In the system taken as a whole there is a fairly constant decrease in proliferation and a fairly constant, but not homogeneous, increase in differentiation throughout the entire developmental period.

Acceleration in rate of differentiation is correlated with retardation in rate of proliferation and vice versa, except for the third interval in the spinal cord.

During the first interval of development there is an increase of differentiation throughout the system which is far greatest in the cerebrum. This is a period of acquisition of new adaptability to environment. During the second interval the greatest acceleration of differentiation is in the rhombencephalon marking an extension and perfection of the responses acquired before. In the third interval the greatest acceleration is in the cerebrum, correlated with the development of locomotion.

Acceleration of differentiation in the cerebrum is correlated with acceleration in the spinal cord and occurs during periods of particular development of longitudinal conduction paths, while retardation of the poles of the system is correlated with marked acceleration in the rhombencephalon during the second interval, when there is particular development of transverse conduction in that region.

There appears to be a wave of acceleration of differentiation, originating in the cerebrum and progressing caudad; a second wave beginning as the first reaches the spinal cord. This suggests that accelera-

tion of differentiation may be rhythmic and a factor in the orientation of neuroblasts and the outgrowth of conduction paths.

The results of these investigations indicate that an exhaustive study of this nature during the earlier periods of development would probably throw new light upon the problem of control in the development of the nervous system.

24. Sex gland transplantation and the modifying effect in rats and guinea pigs. CARL R. MOORE, University of Chicago.

In the white rat, testicular tissue grafted into young, spayed females will persist for a period of nine months. Associated with the testicle graft the behavior of the animal is decidedly male-like.

Ovaries transplanted into young, castrated males will persist and grow for several months. Such an animal, as an adult, exhibits a maternal behavior towards the young. Somatic differences between male and female are too slight to be of value in a differential diagnosis of maleness or femaleness.

In guinea pigs, ovaries grafted into young, castrated males persist for several months and are accompanied by certain somatic modifications in the male; the teats of the mammary glands hypertrophy and compare favorably in size with those of pregnant females, though little or no secretion could be expressed. Psychical modifications of the male are not, in my experience, subject to modification.

Testicular tissue grafted into young, spayed females can be recovered nine months later. No mature sperm were present in the seminiferous tubules but active mitoses were common in cells of the germinal epithelium, a considerable amount of which may remain. Females bearing such testicle grafts exhibit the characteristic male sex behavior (psychical modification) and the external genitalia appear male-like (somatic modification).

In the white rat ovarian grafts will persist for eight months in a male with one normal testicle. Graafian follicles continue their development normally up to the maturation period of the ovum. Subsequently the follicles undergo atresia without ovulation.

There appears to be no deleterious influence of secretions from either sex gland upon the opposite one.

25. The development of connective tissue in the chick embryo. GEORGE A. BAITSELL, Osborn Zoological Laboratory, Yale University.

In a previous communication (Proc. Nat'l. Acad. Sci., VI, 1920) the author has shown that the primitive forerunner of connective tissue in frog embryos is an amorphous, gelatinous, intercellular material which begins to form around the notochord at a very early stage and previous to any cell syncytium. This primitive ground substance is difficult to detect but, with the proper staining, it can be demonstrated in the preserved material and also, as shown in a later communication (Proc. Soc. Exp. Biol. and Med., XVII, 1920), it can be demonstrated in living frog embryos.

These studies have been continued with chick embryos and from the results obtained to date it can be said that an intercellular ground substance is present in the chick embryos and can be readily demonstrated in, for example, a 48-hour stage, in both the living and in the preserved material. This is in agreement with the results obtained by Szily in his work with chick and various other embryos (Anat. Hefte, XXXV, 1907) who said that "Vor dem Auftreten der Mesenchymzellen sind die Lücken und Spalten der Embryonalanlage durch ein feines Fasersystem ausgefüllt." He believed, however, that this ground substance was formed as a result of a fusion of cell processes and was therefore in reality intracellular in its formation.

The evidence from the present studies is that this material is formed in the chick embryo as an intercellular secretion. This is in harmony with the previous results, obtained by the author, with amphibian embryos, as noted above, and is in general agreement with the intercellular theory of connective tissue formation, as stated, for example, by Merkel (Anat. Hefte XXXVIII, 1908).

26. Some habits of cirratulus in relation to fertilization. John W. Scott, University of Wyoming.

Previous notes on the development of this annelid were presented in 1911 and 1914. *Cirratulus* lives in the muddy ooze around or near the roots of eel grass and is usually found within two or three inches of the surface. The organic substance in the mud furnishes its food. The breeding season begins early in August and lasts three or four weeks. The cleavage and the behavior of the yolk lobe resemble that of *Dentalium*. At Woods Hole *Cirratulus* is plentiful and easy to collect, but experimental fertilization is difficult due to sensitiveness to external stimuli. Slight mechanical irritation, direct sunlight and, apparently, the presence of the opposite sex, may cause sexual products to be thrown off prematurely. Fully mature eggs are deposited only at night and fertilization occurs at night, or in the morning within a few hours after oviposition. It is possible to secure good material for experimental work early in the morning by handling the worms carefully while collecting, placing each individual in a separate bottle, protecting from sunlight, and keeping each worm isolated over night in a separate finger bowl. Even with these precautions some worms expel immature eggs or sperm. Undoubtedly the worms must come to the surface to discharge their products. So the nocturnal breeding habit is correlated with physiological processes that are active only at night; it is not due directly to a suppression of the reflex by harmful stimuli or we would find ripe eggs in some worms in the day time.

27. Homoplastic and heteroplastic endocrine transplants. W. W. Swingle, Osborn Zoological Laboratory, Yale University. (Introduced by R. G. Harrison.)

A. Pituitary glands (anterior lobe) of adult Rana catesbeiana, Rana pipiens, and young Rana climitans were ingrafted intraperitoneally

into immature larvae of the bull frog averaging 55 mm. in length. Two weeks from date of operation hind limbs appeared. The limbs grew and differentiated rapidly and within 30 days from date of operation averaged 12 mm. in length. The tadpoles increased but slightly in size during 40 days of observation. Body emaciation or tail atrophy was not observed. The fore limbs of but one animal appeared. Chief result was effect of the anterior lobe secretion upon the development of limbs. The growth and differentiation of the limbs is much slower than in case of thyroid grafted individuals of same age and size.

B. Pituitary glands (intermediate lobe) of the three species of frogs mentioned were ingrafted into immature larvae. Within 48 hours the experimental animals had changed color from a golden yellow to almost black. This dark pigmentation was retained for eighteen days when most of the larvae resumed normal coloration over night. The larvae showed no increased growth or limb development. Chief result, the effect of the secretion of the intermediate lobe of the pituitary upon the expansion of the Melanophores of the skin.

C. The posterior lobe of the pituitary of three species of frogs ingrafted intraperitoneally into 60 mm. larvae. After 38 days the larvae had not only failed to grow but appeared very much emaciated. No change in pigmentation or limb development occurred. Result: cessation of growth and emaciation.

D. Adrenal glands (cortex and medulla), the paraphysis, and Kiemen Reste were ingrafted with negative results in every case.

E. Thyroid grafts either homo- or heteroplastic are by far the most effective of the endocrine glands in inducing metamorphosis both in regard to the time required and extent to which metamorphic changes occur. Thyroid glands of neotenous larvae are inactive and fail to induce evidences of metamorphosis even when several such glands are ingrafted into the same individual.

It is possible to ingraft a thyroid into an immature larva, induce metamorphosis, re-ingraft the same gland into another larva, induce metamorphosis, then repeat the process again on yet a third animal thus passing the same graft through three individuals.

28. Is the initiatory effect of egg secretion specific? ALVALYN E. WOODWARD, Amherst College. (Introduced by O. C. Glaser.)

Experiments are described in which egg secretions of *Asterias*, *Arbacia* and *Echinarachnius* have initialed development in eggs of another phylum, namely, on the worm, *Nereis limbata*.

CYTOLOGY

29. Cytology of Anisolabis maritima. (Lantern.) S. I. KORNHAUSER, Denison University.

The chromosomes of the Forficulidae have been described as extremely variable, and the sex chromosome complex as diverse. Thus a detailed study of Anisolabis was undertaken. The diploid chromo-

some number has been determined with certainty as being twenty-five in the male, and twenty-six in the female. The metaphase plates of the first spermatocyte present a puzzling picture, inasmuch as only twelve chromosomal bodies are to be found. On careful analysis it was found that one of the twelve chromosomal bodies was a hexad, the X-chromosome being attached laterally to one-half of an autosomal tetrad. It passes undivided to one of the second spermatocytes. In the interkinetic period it separates so that half the metaphase plates of the second spermatocytes show thirteen chromosomes and half twelve.

In oogenesis each oocyte is accompanied by a single nurse cell. The oocyte and nurse are sister cells, the differentiation being brought about by a cytoplasmic inclusion. Each nurse cell remains attached to its oocyte by means of a root-like outgrowth which extends nearly to the nucleus of the oocyte. During the period of syndesis, the oocyte grows at the expense of the nurse cell, and then as soon as parasyndesis has been effected the nurse cell grows very much more rapidly than the oocyte, the smaller cell of the two preceding in the journey down the ovarial tube. Later on the proportions of the two are again reversed, and finally the nurse cell forms merely a cap anterior to the oocyte.

30. Protoplasmic viscosity changes in the dividing egg of Cumingia. L. V. Heilbrunn, University of Michigan.

Earlier study showed protoplasmic viscosity changes during mitosis. The attempt has now been made to determine the magnitude of these changes and their exact time relation to the mitotic process. Eggs of the lamellibranch Cumingia were centrifuged at short intervals during the time which elapses between fertilization and cleavage. By centrifuging at varying speeds it was possible to determine with some degree of accuracy the comparative viscosity at different stages. At fertilization the egg is in the metaphase of the first polar body mitosis, and the viscosity of its protoplasm is relatively low. Just before the first polar body is given off, the viscosity increases eightfold, it then falls to its original value, increasing eightfold again as the second polar body is given off. This is followed by a slight drop, then a rise in viscosity in the early prophase of the cleavage mitosis. Just before the pronuclei break down, at a stage presumably shortly after the first appearance of the cleavage spindle, the protoplasmic viscosity decreases rapidly until it is as low as in the unfertilized egg. Finally two or three minutes before the cell divides the viscosity suddenly increases until it is nine times that of the unfertilized egg.

31. The structure and division of Trichomonas muris (Hartman). D. H. Wenrich, University of Pennsylvania.

This flagellate protozoon from the coecum of mice is 12-16 microns long by 5-10 microns wide and possesses the following organelles: nucleus; cytosome; and the blepharoplast with its attached structures, the three anterior flagella, the posterior flagellum running as the

margin of the undulating membrane, the chromatic basal rod at the base of the undulating membrane, the axostyle, the outer and inner rows of chromatic granules, and the parabasal body. This last named structure is the true parabasal of Janicki ('11) but appears only after certain methods of technique.

In division, stages comparable to the prophase, metaphase, anaphase and telophase of metazoan cells can be recognized. During prophase, six double (split?) chromosomes are formed, while the caryosome gradually disappears like the metazoan nucleolus. The new chromatic basal rod arises as a row of fine granules with one end of the row attached to the blepharoplast. The new undulating membrane and posterior flagellum develop along with the new chromatic basal rod. A small new blepharoplast is budded off from the parent one and the two remain connected by the paradesmose during division. The nuclear membrane persists throughout mitosis. The behavior of the chromosomes during metaphase and anaphase is similar to that in metazoan cells. The old axostyle degenerates and a new one grows out from each blepharoplast. A new row of chromatic granules is budded off from the inner margin of the chromatic basal rod. Division of the cell body is delayed until two sets of organelles are complete. The nucleus and the cell body are the only parts to divide equationally, all other needed parts being supplied as new outgrowths.

32. A comparison of a Limax Amoebae with tissue culture cells. M. J. Hogue, School of Hygiene and Public Health, Johns Hopkins University.

These amoebae from a 'pure mixed line' average 20μ in their long diameter. They are much smaller than the fibroblasts of an embryonic chick heart which average 50 μ in their long diameter. The fibroblasts attach themselves to the coverslip and spread out very flat, their fine endings being invisible. The amoebae, when grown on agar agar, are flat but they always have a definite outline. The locomotion of the amoebae is visible while that of the fibroblasts is too slow to be noticeable.

When stained with neutral red, both amoebae and fibroblasts have neutral red granules and vacuoles. Neutral red channels have not been seen in the amoebae. Both kinds of cells have mitochondria which stain with Janus black no. 2. In the fibroblast their shape varies greatly from round balls and short rods to long branched forms. In the amoebae only spherical and rod shaped mitochondria are found.

Brilliant crysl blue, methylene blue and neutral red were all used. The stain for the fibroblasts killed the amoebae. After diluting each stain to one-fourth its strength, it colored the amoebae without killing them and gave the same results as the stronger stains did with the fibroblasts. The amoebae is much more sensitive than the tissue culture cells.

33. Unusual tetrads and their bearing on the problem of crossing-over. W. R. B. ROBERTSON, University of Kansas.

Among the ring-like tetrads resulting from the pairing of compound chromosomes, such as occur in Chorthippus curtipennis, there have been found again cases of a condition in which the two strands of one of the members of a pair show one complete revolution about each other which is not present in the strands of the other member of the pair. This torsion occurs, of course, in a region of the tetrad where disjunction has taken place—that is, at an internode between two points of the tetrad which are still in conjunction.

This may mean 1) that the pairing chromosomes were each split and the halves independently twisted about each other before parasynapsis took place, (Robertson, '16, p. 257); or 2) that crossing-over between one strand of each of the conjugants has taken place at some previous time.

If the latter be the correct interpretation, then opposite sides of the ring would each receive one strand of the paternal and one of the maternal pair, and the first division be accordingly equational for the bulk of the tetrad.

The important point, however, is that the crossing-over hypothesis gives a very satisfactory explanation of the abnormality.

34. Spermatogenesis in Cestodes. R. T. YOUNG, University of North Dakota.

Continued investigation of the origin of the sperm cells in cestodes indicate the degenerate character of this process. An abortive maturation mitosis occurs. The spireme breaks up and is distributed through the cytoplasm of the spermatocytes. These fuse to form a cytophore and the sperms appear to arise from the spireme fragments.

35. Conjugation and fission-rate in Arcella vulgaris (Ehrenberg). HANSFORD M. MACCURDY, Alma College.

In pedigreed cultures of Arcella vulgaris under laboratory conditions the fission rate varies considerably. A general average rate in a non-conjugating line derived from one parent cell was one division for every 2, 56 days. At times when estimated for weekly periods, the fission rate for any one line would increase for a period giving a higher rate and this would be followed by a period of slower divisions. The rate in a parallel line might not be the same.

Conjugation was most often found to occur at times of low fission rate. In many cases this was found to occur at intervals of about a month. There are exceptions. Many exconjugants gave a higher rate of division for a period following conjugation than parallel lines gave for the same period. Some non-conjugants gave a higher rate than some ex-conjugants. Certain nuclear conditions are pointed out and their probable significance considered.

36. The occurrence of precocious and abortive maturation phenomena in female larvae of Rana catesbeiana. W. W. Swingle, Osborn Zoological Laboratory, Yale University. (Introduced by R. G. Harrison.)

The writer has shown in earlier work on the germ-cell-cycle of male Rana catesbeiana larvae, the occurrence of a precocious and abortive sexual cycle which culminates in degeneration and resorption of most of the germ cells derived from the primordial entoderm (Keimbahn cells). This larval sexual cycle occurs in immature male tadpoles 45–60 mm. total length, animals which have a year or more of larval life before metamorphosing. Following the degeneration of the spermatocytes, a new generation of germ cells arises, presumably by proliferation of the few lineal descendants of the Keimbahn cells which persist unchanged through the abortive maturation cycle. This new cell generation in many tadpoles just at the time of metamorphosing undergoes a second sexual cycle culminating in the production of normal spermatozoa in the tadpole. The first larval sexual cycle is abortive in almost every feature: great size of the spermatocytes; Urodele type of tetrad, and behavior of the centrosome. The second larval sexual cycle is normal.

Similar phenomena occur in female tadpoles of the same size and age. In undoubtedly female larvae, many of the young oöcytes at the beginning of the growth period pass through all the stages of diakinesis and form first maturation chromosomes of very large size. Most of the cells degenerate at the time of spindle formation owing to the formation of polyasters. In a few cells the maturation process goes as far as the anaphase of the first division, when the spindle apparatus breaks down. The spindles are not eccentric in position, but run from pole to pole of the cell. The tetrad complexes are very large and of the open ring or Urodele type, and bear no resemblance to the rather small dumbbell shaped tetrads characteristic of adult anurans.

It is suggested that the phenomena described here constitute a recapitulation in the germ-cell-cycle of past phylogenetic conditions when the Anura were permanently of the caudate type and reproduced as tad-pole-like forms.

37. Peculiar chromosomal phenomena in a Homopteran. Franz Schrader, University of Michigan. (Introduced by L. V. Heilbrunn.)

In Pseudococcus nipae, a Homopteran, both sexes have a diploid number of ten chromosomes. In the female, five tetrads are formed and reduction results in the haploid number of five chromosomes as in the ordinary manner. In the male, the growth stages of the spermatocytes show five of the ten chromosomes condensing in advance of the remaining chromosomes. These five chromosomes can be identified in following stages by the tendency to remain in a more or less clumped group. No trace of tetrad formation could be found. The first spermatocyte division is equatorial and ten chromosomes go to each pole. The second division is reductional and this apparently takes place in that the five clumped chromosomes go to one, and the remaining five

to the opposite pole. Early spermatids still show five chromosomes and the formation of spermatozoa seems to follow ordinary lines.

38. The early history of the germ cells in the brook lamprey, Entosphenus wilderi (Gabe), up to and including the period of sex differentiation. PETER OKKELBERG, University of Michigan. (Introduced by Paul S. Welch.)

The germ cells are segregated before the germ layers are definitely established. They are first recognized about the time when the mesoderm separates from the entoderm (embryo about 191 hours old). The definitive germ cells, in both sexes, take their origin from these primordial germ cells and from no other source. Numerous germ cells degenerate in every individual and they never take part in the formation of somatic structures. During the period of sex differentiation two types of cells are found in practically every individual, those which continue to divide and those which stop dividing and enter upon a synaptic and growth phase. The former are taken to be potential male cells (spermatogonia) or indifferent cells and the latter potential female cells (primary oocytes). The relative proportion of the two kinds of cells apparently determines whether the larva shall become a male or a female. Observations seem to warrant the conclusion that each larva carries in it the potentiality of both sexes and that sex, therefore, is not irrevocably fixed at or before fertilization. When a larva becomes definitely established as a male or as a female the opposite sex cells disappear except in the male where rudimentary eggs are frequently found in the adult testis. In the adult condition the number of individuals of each sex is about the same.

GENERAL ZOÖLOGY

39. Something of the life history of a fresh-water medusa. F. PAYNE, Indiana University.

September the twenty-second, 1919, I was notified of the presence of fresh-water medusae in a small artificial lake near Elkhart, Indiana. September the twenty-seventh I visited the lake and found medusae by the thousands. Two weeks later not a medusae could be found. Apparently the cold weather caused their disappearance. All specimens examined were females. A few specimens had been seen the previous summer. The lake, an abandoned clay pit, has been stocked with fish, most of which came from Indiana, but one lot came from a hatchery in Mississippi.

The past summer the lake has been followed closely. The hydroid stage was found and the medusae reappeared. The hydroids have been seen to give rise to sausage shaped buds which break away and develop into other hydroids. Other buds of an entirely different type develop into medusae. The larger medusae have been followed in an attempt to distinguish sexes. Again as in the previous summer only females were present. An examination of posts, limbs, floating

wood, etc., as well as plankton catches at various depths revealed no traces of a larva. So the questions of the males and the development of the eggs into the hydroid still remain unanswered. One is inclined to ask whether the hydroids may not be male and female producing.

In all other finds reported the specimens were all males. The genus is no doubt Craspedacusta. Since seeing the hydroids and medusae I am inclined to think that Craspedacusta and Microhydra are medusa and hydroid stages of one and the same thing.

COMPARATIVE ANATOMY

40. The history of the vertebrate mouth. H. V. Neal, Tufts College.

That the hypophysis of vertebrates represents a paleostoma has been assumed by morphologists on the basis of embryological evidence, supported by that of its functional persistance as an opening in some adult cyclostomes. This hypothesis is still further strengthened by the evidence presented in this paper that the hypophysis is the homologue of the larval mouth (tremostoma) of Amphioxus. The present vertebrate mouth may therefore be considered as the third—or the fourth, if the neuropore be added—mouth in chordate phylogenesis.

41. The origin of the cerebral hemispheres. C. Judson Herrick, University of Chicago.

Assuming that the telencephalon of vertebrate ancestors was the most rostral portion of a neural tube whose walls were uncomplicated by local thickenings or evaginations, it is evident that in different groups of fishes cerebral differentiation has followed several divergent lines. In some ganoids (Acipenser, Amia) and in all teleosts a portion of the lateral wall of the telencephalon adjacent to the lamina terminalis has evaginated to form the olfactory bulb and the remainder of the telencephalon is variously thickened without evagination. The evaginated portions only are the true cerebral hemispheres and the remainder may be termed the telencephalon medium or primitive endbrain. In all vertebrates these two subdivisions of the telencephalon can be recognized, and as we pass from lower to higher forms a progressively larger proportion of the primitive endbrain is joined to the olfactory bulbs in the evaginated cerebral hemispheres.

Some very generalized fishes have, however, extensively evaginated thin-walled cerebral hemispheres instead of massive local thickenings in the primitive endbrain; and this thin-walled form may have been better adapted to oxygenate the brain among the primitive mudfishes which inhabited the drying lakes and streams in the period of increasing aridity of late Silurian geological time and from which the Amphibia arose. After the acquisition of efficient pulmonary respiration in the Amphibia the evaginated cerebral hemispheres, now well supplied with oxygenated blood, differentiated progressively along lines impossible to animals whose forebrain patterns had been stabilized on the teleostean plan.

42. The integumental glands of Alligator mississippiensis. A. M. REESE, West Virginia University.

Three sets of integumental glands are found in the alligator: the dorsal glands, of uncertain function, and two pairs of musk glands.

The dorsal glands are minute spherical structures that are found just under the skin in two rows, one on either side of the mid-dorsal line. They open to the surface through minute pores. They develop as thickenings and invaginations of the lower layer of the epidermis. The wall of the adult gland consists of a sort of loose, stratified epithelium, resembling somewhat the stink gland of the turtle. Since these glands are very small and have, so far as could be determined, no odor, they probably have some other function.

Of the musk glands, the pair that opens into the cloaca is the larger, though the glands that open by a slit on either side of the ventral wall of the throat are of considerable size in large animals. Like the dorsal glands, the musk glands are developed by an invagination of the lower layer of the epidermis, and their walls are composed of somewhat similar though more compact layers of cells. The secretion, or musk, is a smooth, oily substance with the powerful odor characteristic of that well-known extract, and is doubtless used by the sexes, both of which produce it, in locating and following each other during the breeding season, when the glands are said to be most active.

43. The order, time and rate of ossification of the vertebrate skeleton. R. M. STRONG, Loyola University School of Medicine.

This is a preliminary report of work in progress on material representing the Amphibia, Reptilia, birds and mammals. In this paper only the work with birds and mammals is considered.

Considerable similarity has been found in the order of ossification, but there are definite differences and some individual variability. In general, the long bones of the limbs show the first ossification. Centers appear about the same time in the clavicle, maxilla, and mandible.

The time of beginning ossification varies greatly in different groups and even in orders. In the birds, the variation is only a few days though the incubation period varies greatly. The first ossification centers appear in the chick about the eighth day of incubation, but not until about the seventeenth day in the rat embryo.

Certain bones vary greatly in the time of ossification. Thus the sternum of the chick embryo begins to ossify about the sixteenth day, but only traces of ossification appear in the duck at about two months after hatching or three months from the first incubation. The white rat sternum has ossification centers on the twentieth day, only about three days after the first centers appear in the rat skeleton.

The rate of ossification varies greatly. It is somewhat more rapid in the chick than in the duck and much more rapid in the rat.

Some observations have been made from the standpoint of the metabolic gradient theory of Child. Ossification is successively later in the vertebrate posteriorly. On the other hand, the appendicular skeleton

precedes the axial slightly, and the distal phalanges ossify before the next row proximally.

44. Primary neuromeres and vertebrate head segmentation. H. W. STUNKARD, New York University. (Introduced by J. S. Kingsley.)

The examination of large numbers of embryos has shown that in Amblystoma and the chick at least, the structures described by Locy and Hill as primary segments can not be regarded as metameric. A repetition of their work, using as far as possible identical means of examination, has in the present case not only failed to verify their findings, but discloses a quite different condition. The three morphological features upon which neuromerism can be based, marginal beadings, external and internal grooves, and cell arrangement, all fail to give evidence to confirm the primary neuromerism of Locy and Hill.

Griggs also endeavored to establish neuromerism as a basis for determining the segmentation of the vertebrate head, describing neuromeres in the procephalic part of the open neural plate of Amblystoma embryos. The median divisions observed in the neural plate of Amblystoma embryos are largely if not entirely due to segmentation of the mesoderm, and can be regarded only as features of secondary importance.

The primary neuromeres of Locy and Hill as well as those of Griggs and other students of neuromerism are irregular in size, inconstant in number, asymmetrical in position, and can not be accepted as trustworthy criteria of the metamerism of the vertebrate head.

45. Studies on lymph nodes: I. Structure, as shown by deposited ink granules. THESLE T. JOB, Loyola University School of Medicine. (Introduced by R. M. Strong.)

Subcutaneous injections of India ink are allowed to be taken up by the lymphatic vessels for varying lengths of time. The course of the ink granules is then traced.

By this method it is possible to show that the posterior or distal part of the node becomes thoroughly congested with ink granules before the anterior or proximal part. In many instances the anterior part never becomes tinged with the ink. The peripheral sinus is not a continuous space over the whole node. The afferent lymph vessels are few in number and enter the periphery at or near a median, longitudinal plane in the posterior part of the node.

Microscopical sections show the distal part of the node more sinusoidal than the proximal part. The proximal part contains more lymph follicles.

46. The topography of the cloaca of the male Necturus in relation to the cloacal glands. ALDEN B. DAWSON, Loyola University School of Medicine. (Introduced by R. M. Strong.)

The external opening of the cloaca of the male Necturus is a longitudinal slit bordered by two inconspicuous lips which, at their caudal

ends, give rise to a pair of soft, non-pigmented, papilla-like projections. The lips are modified further by numerous transverse fissures. Immediately dorsal to the cloacal opening is the cloacal chamber or vestibule which is continued cranially as the cloacal tube. The floor of the cloacal tube has the form of a deep trough with the mucosa thrown up into thin parallel ridges which become interrupted caudally and merge into the tall, slender papillae present on the sides of the cloacal chamber. The roof is modified also by the presence of a deep median groove and, on either side of the cloacal tube, between the dorsal depression and the ventral trough, are two longitudinal furrows.

The cloacal cavity is completely surrounded with masses of long tortuous tubular glands. The large median ventral mass is known as the cloacal gland. Its tubules open on the summits of the parallel ridges and on the tips of the slender internal papillae. The masses of the paired abdominal glands lie ventro-laterally to the cloacal chamber, and their tubules open on the medial surfaces of the paired external papillae. Dorsally there is present a median gland mass, the pelvic gland. This gland shows at least four differentiations, distinguished histologically by the character of the epithelium lining its tubules. There is a small median cranial mass, a very large, median, caudal mass and two lateral masses. All the tubules of the pelvic gland mass open into the roof of the cloacal tube.

PARASITOLOGY

47. Measurements of Trypanosoma diemyctyli from different hosts and their relation to specific identification, heredity and environment. R. W. HEGNER, Department of Medical Zoology, School of Hygiene and Public Health, Johns Hopkins University.

This investigation involved 1) the problem of the existence of heritably diverse strains of trypanosomes living in the blood of different hosts of the same species, and 2) that of the effects of different environments as represented by the blood stream of different hosts of the same species. A high percentage of infection with Trypanosoma diemyctyli was found in newts (Diemyctylus viridescens) captured in Pennsylvania. Measurements of total length, of portions of the body, and of width showed that specimens from one host animal differed in these dimensions from those in other host animals. For example, specimens taken at random from newt 19 averaged 68.8 microns in total length whereas those from newt 15 averaged only 45.2 microns in total length. Those from newt 19 were also greater in width measuring on the average 3.5 microns in diameter whereas those from newt 15 were only 2.6 microns thick. The different types of trypanosomes obtained from the different newts may belong to different species, or may be races of one species that are heritably diverse in size, or may be sexual phases of a single species, or may differ because of changes due to the environment. Experiments in this laboratory are now in progress to test these various possibilities.

48. Notes on the development and distribution of Oncicola canis (Kaupp 1909). H. J. Van Cleave, University of Illinois.

Acanthocephala have been reported from dogs in various parts of the world. Most of these instances seem to be accidental infestations by species common in other hosts. *Oncicola canis* (Kaupp 1909) is the only species recorded from the dog in North America. Adults of this species have never been found in any other host. Circumstances surrounding the case first described (Parker 1909) indicate the possible association of this parasite with symptoms superficially resembling rabies. Development of this parasite and source of infestation of the definitive host therefore become matters of considerable importance.

The writer has examined larvae taken from the mesenteries and abdominal peritoneum of the armadillo by Albert Hassall. The identity of these larvae and adults from the original lot of specimen of *O. canis* has been determined beyond doubt. The armadillo probably serves this parasite as intermediate host, not primary host as advocated by Travassos for the South American species of the same genus.

Dependence upon the armadillo in its life cycle explains the sharp restriction in natural distribution of this parasite. The undetermined *Echinorhynchus* listed by Ward (1897) from a dog at Lincoln, Nebraska, has been examined and found to be *O. canis*. This occurrence outside the limits of distribution of the larval host is probably due to some sort of accidental introduction.

Parker suggests that many reports of "mad" coyotes may be due to heavy infestations by this species. Unfortunately data of the occurrence in this host are lacking.

49. Dermatobia hominis. Thomas Bryd Magath, Section on Clinical Laboratories, Mayo Clinic, Rochester, Minn.

This paper deals with a general survey of all the reports found in American literature of the parasite, *Dermatobia hominis*. The morphology, life history and distribution of the parasite is discussed. The author's case is reported in detail and the morphology of the larva found is compared with descriptions made by previous authors.

50. The development of the Japanese blood-fluke, Schistosoma japonicum Katsurada in its final host. W. W. Cort, School of Hygiene and Public Health, Johns Hopkins University.

A study of the development of *Schistosoma japonicum* was made from material from experimentally infected mice. After penetrating the skin of the final host the cercariae lose their larval characters. To attain the largest adult size for the species the cercaria must increase in length over one hundred times. Sexual maturity is reached in about twenty days at which time the parasite has increased in size about thirty times. At stages between 0.3 mm. and 0.4 mm. in the livers of the mice, the males show distinctly larger suckers and a broader body than the females and the females have a broader area in front of the union of the

intestinal ceca. As development proceeds the female becomes narrower than the male and round in cross section, while in the male the post-acetabular region gradually becomes flattened and the sides grow up to form the gynaecophoric canal. Larvae as small as 0.3 mm. were found in the livers of the mice up to eighteen days after infection. Since there is little if any growth in size before the larvae reach the liver, and after reaching that organ a very rapid growth ensues, this finding can only be explained by concluding that there is considerable variation in the time taken for the migration from the skin to the liver. The changes in the various organs during the course of development were traced step by step. Differentiation of the reproductive organs comes very late in development.

51. The course of migration of Ascaris larvae from the intestine to the lungs. B. H. Ransom and Eloise B. Cram, U. S. Bureau of Animal Industry.

Stewart ('17) suggested that the most probable path of migration of Ascaris larvae to the lungs after hatching in the small intestine is as follows: Mesenteric veins, portal vein, liver, hepatic vein, vena cava, heart, and pulmonary artery. Yoshida ('19) however, has reached the conclusion that migration of the larvae by way of the circulation if it occurs at all is merely accidental, and states that the newly hatched larvae penetrate through the wall of the intestine into the abdominal cavity, some of them burrowing into various organs such as the liver, spleen and kidney, while others pierce the diaphragm, enter the pleural cavity and finally the lungs. Yoshida also was led to infer that some of the larvae that enter the abdominal viscera, later return to the abdominal cavity and proceed through the diaphragm to the pleural cavity. Ransom and Foster ('20) have recorded two instances in which Ascaris larvae were found apparently in the portal and pulmonary blood vessels. In some recent experiments in which guinea pigs have been killed and examined during the first few days after feeding with eggs of *Ascaris suum* the present writers have repeatedly recovered Ascaris larvae from the portal vein and vena cava but have rarely found them in the abdominal or pleural cavities. Accordingly, the larvae appear to be not uncommonly carried in the circulation, and it would seem that further evidence is necessary before Yoshida's conclusions as to the direct migrations of the larvae through the tissues can be accepted as final.

52. Life history of a new Limax Amoeba. M. J. Hogue, School of Hygiene and Public Health, Johns Hopkins University.

The amoebae were found in the alimentary tract of the oyster. They were grown on various media made up with agar agar and also in liquid media. "Pure mixed lines" were isolated and studied with vital stains and in fixed preparations. The amoeba averages 20.5μ in its long diameter, though it varies considerably, according to the age of the culture. The nucleus is spherical—averaging 2.5μ. It has a large karyosome which is mostly spherical, but often of irregular shape and

size. There is a clear ectoplasm and an endoplasm which contains large refractile granules. No contractile vacuole is present. The amoebae are actively motile, moving usually by a large anterior ectoplasmic pseudopodium.

Mitosis is promitotic. Endogenous and exogenous buds are formed. Binary fission is common. Many multinucleate amoebae are found and an abundance of multiple division.

Cysts are occasionally formed but they are not of common occurrence. The cyst is spherical with a smooth thin wall. It is always uninucleate. Many attempts were made to produce flagellate forms. All were unsuccessful.

53. Correlation of the life-cycle of a parasite with the metamorphosis of its host. NADINE NOWLIN, University of Kansas, Lawrence.

The gregarine, *Lankestrella sciarai* n.sp., inhabits the digestive system of the small fly, Sciara coprophila. With a few exceptions it follows the typical Acephaline life-cycle, beginning as an intracellular parasite and ending as a free Sporozoite. The point of interest here, therefore, is not in the cycle but in the relation of this development to the three stages of its host: the larva, the pupa and the adult.

In the larva are to be found only the stages from entering sporozoite to adult trophozoite, largely an intracellular career. In the pupa, only pseudo-copulation and early cyst formation occur; and in the adult fly, the true copulation of the gametes and the formation of spores. The limitations of development in the parasite are as definite as are the stages of the host.

In other words, the parasite feeds and grows at the feeding and growing stage of the host; prepares for sexual life at a corresponding stage of the host and completes the sexual program in the fully fledged fly, which is itself sexually mature at this time.

This indicates, I believe, a close physiological control of host over parasite, a condition I have suspected from Endamoeba studies but have been unable to demonstrate until now.

54. Observations on the occurrence and life history of Cephalobium microbivorum (Cobb). JAMES E. ACKERT, Kansas State Agricultural College.

Common black field crickets in the vicinity of Manhattan, Kans., are infested with small roundworms which Dr. N. A. Cobb has identified as *Cephalobium microbivorum*, n. g., n. sp. Eighty-five per cent of the crickets, *Gryllus assimilis*, examined between September 19 and October 31 contained these parasites, the average per cricket being 25.7, and the range in all crickets 2 to 91. Examinations of *G. assimilis* at Woods Hole, Mass., Douglas Lake, Mich., and at Rockford, Ill. failed to reveal a single specimen of *C. microbivorum*, while at Falls Church, Va., Doctor Cobb took several specimens from the common black crickets.

The spacious, thin-walled ileum is the habitat of these parasites which are white and thread-like, measuring from 2 to 3 mm. in

length. Their transparent body walls reveal the internal organs, the uteri containing as many as sixty-six thin-shelled eggs in early cleavage stages. Cricket feces contain eggs in the morula stage. In culture media development proceeds through hatching in a few days, and embryos grow slowly on the addition of 0.8 per cent peptone in Dist H_2O. Both young and adult specimens of *C. microbivorum* occur in the crickets. These parasites may endure the cold weather in the bodies of nymphal crickets (infested in November), some of which survive the winter.

55. Studies on the sheet stomach worm, Haemonchus contortus. JOHN E. GUBERLET, Oklahoma Agricultural Experiment Station.

The stomach worm, *Haemonchus contortus*, is one of the worst enemies of the sheep raiser. Several hundred sheep were treated for the removal of the worms. Copper sulphate, copper sulphate and tobacco, and intra-muscular injections of cacodylate of sodium were used in treating the sheep. Copper sulphate in a 1 per cent solution at the rate of 50 cc. for lambs under one year, and 100 cc. for sheep over one year was found to be 75 to 95 per cent effective. A solution containing 1 per cent copper sulphate and 1 per cent tobacco infusion was found to have an efficiency of 90 to 100 per cent. Cacodylate of sodium was injected intra-muscularly at the rate of 7 grains for an adult sheep. Two or three injections were made at intervals of two or three days with only negative results.

Haemonchus contortus has a periodic seasonal distribution due either to climatic conditions or to the nature of the food at different seasons of the year. Undoubtedly, the nature of the food is a great factor in the gradual removal of some of the worms from the host.

An estimate can be made of the number of stomach worms in the host from the number of eggs in the droppings. Under normal conditions the number of eggs in a gram of fresh droppings corresponds fairly well with the number of adult female worms in the host. There seems to be from 1.5 to 2 times as many females as males. Hence, the number of eggs in a gram of fresh droppings, plus one half to one times that number, gives a fair estimate of the number of adult worms in the host.

56. Acanthocephala from the American eel. H. J. VAN CLEAVE, University of Illinois.

A migratory animal offers many problems with reference to the origin of its parasitic fauna. The parasites of marine and fresh-water habitats usually differ in considerable degree. Among the Acanthocephala few species are common to the two faunas. Because of its wandering between the ocean and freshwater the eel offers exceptional opportunity for a study of the origin of infestation by acanthocephalan parasites.

Various species have been reported from *Anguilla chrysypa*, but many of these have been based upon incorrect identifications. Most of these faulty determinations are due to incomplete descriptions of the older European species which contain little more than generic characters.

Four species of Acanthocephala are known to occur in *A. chrysypa*. A new species, *Tanaorhamphus ambiguus*, was encountered among specimens in the National Museum previously identified as "*E. globulosus*." *Neoechinorhynchus cylindratus* (Van C.) has been reported frequently as the Mediterranean "*E. agilis*." *Echinorhynchus thecatus* Linton and *E. coregoni* Linkins are here reported from the eel for the first time. Of these four species, three occur only in freshwater fishes of North America while the new species represents a genus of which but one other species is known and that parasitizes a single species of freshwater fish.

It is evident that at present the eel does not serve as an agent in mingling marine and freshwater species of Acanthocephala.

EVOLUTION AND GENETICS

57. The production of mosaic males from fertilized eggs in Hymenoptera. P. W. Whiting, St. Stephen's College, Annandale-on-Hudson, N. Y.

An orange-eyed mutation in the wasp, Hadrobracon, acts as a complete recessive to the normal black. Inheritance is "sex-linkoid," the males being haploid and usually parthenogenetically produced. Heterozygous females, isolated as virgin, produce black and orange males in equal numbers. When orange males are mated to black females all offspring are black. In reciprocal mating, daughters are black and most of the sons are orange. A few of the sons, however, are black showing that they come from eggs into which the black-bearing spermatozoon has penetrated. Such anomalous blacks have in some cases bred like black, showing that gonads as well as eyes are paternal in origin. Others have bred like orange, showing that, while eyes are paternal, gonads are maternal. Orange-eyed brothers of anomalous blacks have bred like normal orange, except that in one case such a male bred like a black. Any one male when bred to orange female produces either black or orange daughters, never both; showing that gonad is haploid and either paternal or maternal in origin.

58. The direction and frequency of mutation in a series of multiple allelomorphs. Charles Zeleny, University of Illinois.

Full eye, bar eye and ultra-bar eye in Drosophila melanogaster constitute a series of multiple allelomorphs with decreasing facet number and increasing dominance. Bar arose from full and ultra-bar from bar. Observations were made of the direction and frequency of mutation within pure stocks of the members of the series. In the full eye stocks no mutations to bar or ultra-bar were observed during a period of six years among 46,290 counted individuals and among a much larger number of uncounted ones. On the other hand, the reverse mutation from bar to full occurred 52 times among 84,159 individuals or once in 1618, and from ultra-bar to full 5 times out of 8,681, or once in 1736. Correspondingly there were only three mutations of bar to ultra-bar, including the original mutant, among 84,159 individuals or one in 28,053 while the reverse mutation of ultra-bar to bar occurred three times in

8,681 or once in 2,894 and was observed also at another time when the number of individuals examined was not being recorded. Selection for high or low facet number had no effect upon the frequency of any of the mutations.

In this allelomorphic series therefore 1) reverse mutations are much more frequent than the original ones, 2) original progress to ultra-bar is through bar but reversion may go back directly to full as well as through bar and 3) the frequency of mutation is independent of upward or downward selection.

59. On the relation of stale sperm to sterility and sex in ring-doves. Oscar Riddle and Ellinor H. Behre, Station for Experimental Evolution.

The very abnormal sex ratios obtained from hybrid birds by several investigators require the study of all factors possibly concerned. Practical work in pigeon hybridization also sometimes requires a knowledge of the length of time the sperm may remain alive in the female oviduct. On the latter point we find the spermatozoa of the ring-doves (mostly fully fertile hybrids of closely related species) used by us retained their fertilizing power during very nearly eight days, reckoned from the time of isolation of the male to the hour the egg is laid.

"Staleness" of the spermatozoa did not appreciably affect the sex ratio in 213 individual tests made with a dozen pairs of birds. The degree of staleness was known in each test. Some of the sex ratios obtained during the experiment cannot be considered normal but these abnormal ratios have been shown to be associated with other factors investigated earlier. The abnormal sex ratios that have been obtained in previously reported investigations on these doves, and any results that may be later obtained from them or from similar birds, are here shown to be not complicated by effects due to staleness of the spermatozoa.

60. Genetic analysis of low crossover stock produced by selection. J. A. Detlefsen, College of Agriculture, University of Illinois.

Following selection for low crossover values in red-eyed long winged females (Drosophila melanogaster) heterozygous in white miniature, a stock was produced which has given crossover values of about 5 6 per cent for these two genes. The normal value used in plotting chromosome maps is 33 per cent. Matings of red long females from low crossover stock to white miniature males of normal stock gave F_1 females which show an intermediate value. When the F_1 sibs were mated inter se, the total F_2 results also showed an intermediate crossover value. However there was a distinct increase in the range of values.

Matings of red long males from low crossover stock to eosin miniature females of normal stock gave similar results.

61. A note on inheritance of polydactylism in cattle. E. Roberts, College of Agriculture, University of Illinois.

A normal bull mated to a polydactylous cow produced a polydactylous female. This daughter produced from matings to a normal bull, three calves all of which showed the polydactylous condition.

62. *Selection in Cladocera* (Lantern). ARTHUR M. BANTA, Station for Experimental Evolution.

Some years ago the writer undertook experiments in selection in parthenogenetic pure lines of Cladocera on the basis of a purely physiological character, reactiveness to light. Sixteen lines were subjected to selection for various periods extending over from 18 to 196 generations. In seven of these lines there did not appear any difference in reactiveness between the two strains of the same line. In two lines slight divergences in reactiveness were in the reverse of selection. These divergences, while not large, were fairly consistent. In one of these cases the divergence decreased as the experiment progressed. In five lines there was a possible effect of selection but the evidence is not considered conclusive. In two lines an effect of selection is rather clearly indicated. In one of these the divergence was not large and this case may be disregarded. But in the other the effect of selection is very large and is clearly substantiated. The divergence in this line appeared slowly and increased gradually until during the last months of the experiment the reaction time of the low strain was less than a third that of the high strain. The difference in reactiveness to light was permanent or at any rate persisted for 32 months (112 generations) after selection was discontinued. Return selection was not attempted.

A second series of selection experiments based on an entirely different character is now under way. The character used is the degree of intergradedness of sex intergrade strains of Daphnia longispina. Derived from a common progenitor and reproducing solely by parthenogenesis this would seem a most excellent material for a study of selection. Three strains were selected as high strains and three as low strains, the high and low strains being taken alternately from the six available sister strains. Selection was effective in each case, the individuals of the high strains becoming as high (i.e. as male) as they could be maintained with fair reproductive ability; and the low strains approaching very nearly the condition in which sex intergradedness is not apparent, i.e., most of the individuals showed no sex intergrade characters and the few intergrades were slightly affected. While the facts are as stated, environmental or other factors are influential to such an extent that the curves for the different strains fluctuate somewhat. Further, selection is not effective with equal promptness in every strain though in all cases it has ultimately been effective.

Return selection is also effective. Through selection low strains have been derived from the selected high strains, and high strains from the selected low strains. Two strains have in turn been selected low strains, selected high strains, and selected low strains again.

Thus selection and return selection are equally effective with the amount or degree of sex intergradedness in Daphnia longispina.

63. A study of the character and mode of origin of eighteen mutations in the X-chromosome of Drosophila. H. J. MULLER, University of Texas and E. ALTENBURG, Rice Institute.

Since the eighteen mutants found in the experiment of the writers on mutation frequency were nonselected or random samples of (detectable) mutants in the sex-chromosome, a study of them furnishes quantitative data bearing on the nature of mutations. 1) All were lethals or sublethals. Of the five sublethals four produced morphological abnormalities. 2) All were completely recessive except one mutant of the yellow mouse type. 3) Half of the loci involved are crowded into the 1.5 units space to the left of white eye (the rest being scattered rather evenly). This indicates that this region of the chromosome is really much longer than the map represents. 4) All the lethals gave negative tests for 'deficiency;' hence deficiencies are evidently much rarer than ordinary lethal mutations. 5) Three lethals were allelomorphs of known non-lethal factors, and two of these lethals were allelomorphs of each other. Of the latter one became dominant in its lethal effect when crossed to a non-lethal allelomorph. 6) Lethals very near 'duplicated' loci remained unaffected by the 'duplication.' 7) Mutation occurs with not markedly different frequency in the two sexes, for seven of the lethals were found in the maternal, eleven in the paternal chromosome. 8) These mutations occur not only near maturation, but also in earlier germ cells, in either sex, as shown by the original appearance of some of the lethals in two sisters simultaneously. 9) Two of the original mutant individuals contained two different lethals at once; in one case these were in opposite chromosomes, in the other case in the same chromosome.

64. Further studies on inheritance of color in the turkey. W. R. B. ROBERTSON, University of Kansas.

The pattern of the black variety is allelomorphic to the pattern of the bronze. Black is almost, not entirely, dominant, there being usually about half-a-dozen bronze feathers widely distributed. F_1 black (bronze) ♂ back-crossed to his bronze dam gave 50 per cent of F_2 bronze and 50 per cent black. An F_1 black (bronze) ♀ by a bronze ♂ gave the same result. The bronze of F_2, mated inter se, gave only bronze, the F_1 blacks gave black and bronze.

Black is likewise allelomorphic to the bourbon red and the narragansett patterns. A bourbon red ♀ by an F_1 black (bronze) ♂ gave 50 per cent bronze-red intermediate, like F_1 of the bronze-by-red cross and 50 per cent a rusty black. An F_1 black (bronze) ♀ by a bourbon red ♂ gave 50 per cent bronze-red intermediate and 50 per cent rusty black. The latter shows a slight trace of barring with white in the primaries. A narragansett ♀ by an F_1 black (bronze) ♂ gave 50 per cent black and 50 per cent bronze.

The last cross shows also that the narragansett pattern is probably allelomorphic to bronze. Narragansett is also likely allelomorphic to bourbon red. Reciprocal crosses gave F_1 much like the narragansett

but with subterminal black bands less intense and slaty regions slightly auburn.

These four patterns evidently form a system of quadruple allelomorphs.

White is recessive to color. A white ♀ by a bourbon red ♂ gave F_1 all bronze-red intermediate. She evidently carried bronze but lacked the factor for color. White ♂ by bronze ♀ gave bronze. F_2 was 75 per cent bronze and 25 per cent white.

65. Experiments with typhoid agglutinins in rabbits. M. F. Guyer and E. A. Smith, University of Wisconsin.

Experiments are being conducted to determine if immunization against germs of disease, practiced generation after generation, will eventually result in a truly hereditary immunity. Rabbits may readily be sensitized with typhoid vaccine followed by the living bacteria so that their blood-serum diluted 320 to 640 times will agglutinate living typhoid bacilli. Females so sensitized may transmit to their young and even to their grand descendants the ability to agglutinate typhoid bacilli in serum diluted from 60 to 160 times.

After two or three months of development the young of sensitized mothers are likely to show what appears to be a spontaneous rise of titre. If, for example, they have been averaging a titre of 80 for some time, it may rise to 120 or even 160. After a few weeks it drops back again. Rise of titre may be produced by the injection of milk into the blood-stream.

Young from a sensitized mother, when nursed by a normal mother retain a fairly high titre for several months and may even show the spontaneous rise of titre mentioned. Young of a normal mother, when nursed by a sensitized mother acquire a fairly high titre, presumably from the milk of the foster-mother, but lose it rapidly after weaning time.

66. Flat-fish with unusual pigmented areas. (Lantern). Arthur M. Banta, Station for Experimental Evolution.

During the past season many flat-fish have been taken at Cold Spring Harbor which possess more or less pigment on the functionally under (the left) side. In these individuals the pigment region varies from a mere line in the middle region of the caudal fin to complete pigmentation of the under surface except for the head and a small portion of the adjacent body surface. A majority of the unusually pigmented smaller individuals have pigment over a third or more of the under side.

The abnormally pigmented individuals are almost all rather small and are presumably of this season's spring hatch. From an examination of several lots of smaller individuals, altogether about a hundred, approximately one-fourth were found to possess more or less of the unusual pigment distribution. Among about thirty larger individuals examined, presumably of a previous season's hatch, two were

seen with small amounts of pigment caudally. In one of these the pigment was confined to an antero-posterior line in the middle of the caudal fin. In the other the fin and a very little of the caudal body region was pigmented.

All individuals possess normal pigment on the upper side. The pigmented regions on the under side are indistinguishable in appearance from the upper side except at the limits of the pigmented areas. The abnormally pigmented regions are usually rather abruptly defined though there is a slight gradation in density of pigmentation at the margin of the unpigmented areas. The flat-fish possess a black and a reddish brown pigment. At the margin of the pigmented region on the under side the two pigments are not always equally extensive and small patches occur in which only one of the pigments is represented. Wherever either or both pigments occur the amount of pigment present is apparently normal except for a slight grading out at the very edge of the pigmented area.

Six to eight years ago, and to some extent more recently, the writer saw many of those fish but failed to see any with any pigment on the under surface. Fishermen state that they have seen flat-fish "black on both sides" before the present season but agree that they were much less abundant than now. They claim to have seen individuals this season "black all over both sides" but the writer has not seen such.

Flat-fish with more or less pigment on the functionally under side have several times been mentioned in the literature. The points of interest in the present instance, aside from the variation itself, are the occasional segregation of the two pigments near the limits of the unusual pigmented regions, and the abundance of the variation at Cold Spring Harbor during the present year whereas it was at most quite unusual a few years ago.

67. *A new type of sex-linked lethal in drosophila.* David H. Thompson, University of Illinois. (Introduced by Charles Zeleny.)

A new sex-linked recessive factor has appeared which kills females in double dose and can be recognized in the males which it does not kill. In these males it affects the mesothorax since the wings are held erect and the second pair of legs is feeble. Crosses between heterozygous females and erect males give a sex ratio of one female to two males while other lethals give ratios of two females to one male. Linkage experiments indicate a locus of about 38 in the sex chromosomes. The lethal effect and the character "erect" are manifestations of the same factor as indicated by the absence of crossing over between the two. This erect lethal kills females homozygous for it while other sex linked lethals kill males. The possibility is offered of producing balanced lethals in the sex chromosomes. Recently a dominant accessory factor has appeared which makes erect dominant in the heterozygous females.

68. The course of evolution in the king snakes. FRANK N. BLANCHARD, University of Michigan. (Introduced by Paul S. Welch.)

The twenty-nine recognized species and subspecies of king snakes, distributed from Canada to Ecuador, present a wide range of variation in structure and color pattern. They afford, therefore, good material for the tracing out of genetic relationships on the basis of structure and distribution.

The conclusions arrived at are based on a careful study of constancy and variation in scutellation, color pattern, and other features, of nearly all the specimens of the genus in American Museums. It is evident that the genus is naturally divided into three main groups or sections, one of which is again divided into three more—that the genus therefore includes five groups of directly related forms. The frequently quoted rule that the occurrence of two different forms of the same genus in the same locality is prima facie evidence that they belong to two different lines of descent, and, conversely, that directly related forms are not found in the same locality, is found to hold for this genus, with one exception for which an interpretation is attempted.

It is further particularly noticable in the more diversified groups, the *triangulum* and *getulus* groups, that the forms are related to each other geographically exactly as one not knowing their distribution would expect them, from a study of structure and pattern, to be related if evolution had proceeded from some one form through successive steps to another distinctively different form. Their present distribution, cannot, therefore, be easily accounted for as due to recent speciation in a formerly widespread homogeneous form, but must rather be attributed to orthogenetic differentiation accompanying migration. A study of variation, distribution, and relationship in the king snakes demonstrates conclusively to the writer the direction of evolution and consequently of migration in each of the five groups of directly related forms. These lines of descent all converge to the southwestern portion of the North American continent and this region is therefore regarded as the center of distribution of the genus. The complete paper will appear under the title "A Revision of the King Snakes: Genus Lampropeltis" as bulletin 114 of the United States National Museum.

ECOLOGY AND ZOOGEOGRAPHY

69. The circulation of water in the Bay of Fundy and its bearing on the distribution of the fauna. JAMES W. MAVOR, Union College.

Investigations into the movements of the water in the Bay of Fundy and its approaches, carried on by Dr. J. W. Mavor for the Biological Board of Canada during the last five years, and more especially during the summer of 1919 and still in progress, have shown a general movement of the water which promises to throw considerable light on the distribution and life-histories of the animal life in the Bay.

Three different and independent methods have been applied to the problem: the actual measurements at different points made with cur-

rent-meters by Dr. Bell Dawson have been treated mathematically so as to eliminate the semi-diurnal oscillations of the tidal stream; a large number of drift bottles have been set out; and lastly, a series of hydrographic sections have been made in the Bay, and from the temperatures and salinities at the different stations the velocities at right angles to the sections have been calculated by the hydrodynamic method developed by Bjerknes.

It seems clear from the calculations from Dr. Dawson's tables, from the drift of bottles and from the hydrographic sections, that the water in the Bay of Fundy has a circulation which may be described as follows: water enters the Bay on its eastern side and flows north-east along the coast of Nova Scotia, it crosses the Bay to the New Brunswick side and flows south-westward out of the Bay, the bulk of the water probably passing to the east of Grand Manan. The rate at which the water flows is probably somewhere between 5 and 10 nautical miles per day, so that the complete circuit probably takes from twenty to forty days.

The drift of the bottles, which left the Bay of Fundy set out at various times during the summer, indicated a surface movement of the water from the Bay of Fundy through the northwestern part of the Gulf of Maine and striking Cape Cod, the rate of this drift being about four nautical miles per day.

The movement of the water described explains the distribution of Chaetognaths and young herring as worked out by Dr. A. G. Huntsman for the Bay of Fundy.

70. Geographical distribution of the Anura and their Opalinid parasites. M. M. Metcalf.

The Amphibia give peculiarly valuable evidence as to land migration routes, for they cannot endure salt or even brackish water. The Opalinids are parasitic exclusively in Anura, excepting three species, two of which are known from Urodeles and one, strangely, from a marine fish. The author has studied 130 species and 20 subspecies of Opalinids from all temperate and tropical portions of the world, southern Asia being the only region outside the northern and southern cold belts from which his material is not quite abundant.

Study of this material and comparison with the known data as to the geographical distribution of the Anura indicates:—

1) That the *Raninae* are a northern and eastern hemisphere subfamily, which have not reached Australasia (except for a single species at the northern tip of Australia), and have not reached South America (except for three species which have entered the northern Andes). 2) That the Bufos arose in the northern hemisphere and were not present in Antarctica, Patagonia and Australia at the time when these were united into an Antarctic continent. The Bufos are now in Patagonia. 3) That the Leptodactylidae arose in Patagonia, at a time when Patagonia was not connected with tropical America, and spread *via* Antarctica to Australia. 4) That later than this, Patagonia having

separated from Antarctica and having united with tropical America, the Bufos passed southward into Patagonia and the Leptodactylids passed northward into tropical America. When the Bufos and Leptodactylids met, the Bufos adopted the Leptodactylid Opalinids, while the Leptodactylids did not adopt the multinucleated Opalinids of the Bufos. 5) That the Hylidae arose comparatively late in the Antarctic continent and did not reach tropical America until Patagonia united with tropical America. That having reached the tropical forests of America the Hylids found here conditions favorable for diversification and rapid increase in numbers. 6) That the genus *Protoopalina* is the oldest of the four Opalinid genera and is found in all parts of the world where climatic conditions are favorable, and has in the past been present in both Arctic and Antarctic regions whose climate now precludes the residence of Anura. 7) That the genus *Zelleriella* arose late in Patagonia and has spread a little into Australia. It spread into tropical America after its union with Patagonia. 8) That the genus *Cepedea* probably arose in the eastern hemisphere and migrated to America, possibly by way of Siberia and Alaska, but more probably both by this route and by a direct land-bridge between Africa and eastern Brazil. Cepedea did not come to America from Africa *via* Antarctica. 9) That the genus *Opalina* is possibly a polyphyletic genus and may have arisen in both the eastern and western hemispheres. 10) That some eastern *Opalinae* have migrated to America. 11) That one American *Opalina* has migrated by way of Alaska and Siberia to Asia and across Europe to France. 12) That the multinucleated Opalinids (*Cepedea* and *Opalina*) entered South America from the north or east and are still scarce in southern South America.

71. *Distribution of fishes in Wisconsin lakes.* A. S. Pearse, University of Wisconsin.

The distribution of the fishes in six different types of lakes has been studied. Of the larger fishes, the yellow perch is the most abundant species in four of the lakes (Wingra, Mendota, Green, Michigan). The cisco leads in Green Lake, which is clear, deep, and does not stagnate in summer. In Lake Pepin, which is an expansion of the Mississippi River, the most abundant species are the sand-sturgeon and sauger. Lake Michigan and Lake Pepin, which represent primitive lake habitats for their drainage systems, contain many species that are not found in inland lakes. But many of the species which must have come since glacial times from these great reservoirs attain their greatest abundance in inland lakes. The inland lakes all contain more fishes per unit of area than Lake Michigan or Lake Pepin. The lake (Pepin) in which conditions are most like those in a great river has the fewest fishes per unit of area, but contains the largest number of species. Temperature, depth, stagnation, type of bottom, and the abundance of aquatic vegetation are important factors affecting the distribution of fishes.

72. Data on the distribution of fresh-water sponges in North America. FRANK SMITH, University of Illinois.

The most important work on North American fresh-water sponges has been that of Potts and his co-workers in 1880-1890. The most serious defects in their work were due to the failure to recognize *Ephydatia fluviatilis* and *E. mulleri* as distinct species. The former has gemmule spicules with shafts longer than the diameter of the rotules, and the skeleton spicules uniformly smooth; while *E. mülleri* has the shafts usually shorter than the diameter of the rotules, and the skeleton spicules varying from distinctly spined, sparsely microspined, to nearly or quite smooth. Distinctly spined and smooth spicules are often mingled in the same specimen, and in different ratios in different specimens. In the type the skeleton spicules were described as spined. The varietal name *japonica* has been given to specimens with smooth skeleton spicules, found in Japan, and in 1910 the name *Ephydatia japonica* was applied by Annandale to specimens collected in the Potomac River. Material from different parts of Michigan, Illinois, and high mountain lakes of Colorado indicates: that specimens with smooth, or nearly smooth, skeleton spicules are most abundant, but that the ones with spined spicules are similarly distributed; and also that the same body of water may contain both of these kinds of specimens, and still others with spined and smooth spicules mingled in the same skeleton fascicles. *E. fluviatilis* has a similar distribution, but is less abundant than *E. mülleri*.

73. Quantitative and chemical studies of the plankton of Lake Mendota. (Lantern.) C. JUDAY, Wisconsin Geological and Natural History Survey.

These studies were made between April, 1915 and June, 1917. The larger forms, designated as net plankton, were obtained with a regular plankton net, while a centrifuge was used to recover the minute forms, called the nannoplankton. Numerical studies as well as gravimetric determinations were made on both kinds of plankton.

The quantity of dry organic matter in the net plankton varied from a minimum of 73 mgm. per cubic meter of water to a maximum of 1,135 mgm. The average amount for the period covered in these observations was 343 mgm. per cubic meter. Maxima were found in June and November in 1915 and in June and December in 1916. The minima came in April and July–August in 1915 and in March and August, 1916.

The dry organic matter of the nannoplankton varied from a minimum of 795 mgm. per cubic meter of water to a maximum of 3,151 mgm.; the average quantity for the period was 1,630 mgm. The maximum quantity was obtained in April, 1915, and 1916 and in May, 1917. Minima were found in August and early September. The quantity of nannoplankton was always larger than that of the net plankton, but observations on other lakes show that it may be smaller at times.

The net plankton and nannoplankton combined, or the total plankton, gave maxima in April and in October in 1915, with a minimum in August. In 1916 the maxima came in April and late September, with a minimum in late August and early September. During the first half of 1917, there was a minimum in March and a maximum in May.

For the area enclosed by the 20 meter contour line, the dry organic matter of the total plankton ranged from a minimum of about 258 kgm. per hectare (230 pounds per acre) in February to a maximum of 521 kgm. (465 pounds) in December. For the entire lake the former figure is reduced to 141 kgm. per hectare (126 pounds per acre) and the latter to 287 kgm. (256 pounds).

Nearly 53 per cent of the dry organic matter of the net plankton consisted of crude protein and more than 12 per cent of ether extract. The nannoplankton was poorer in nitrogen and ether extract, yielding a little less than 43 per cent of crude protein and 6.5 per cent of ether extract. In the total plankton the crude protein amounted to 44.5 per cent of the dry organic matter and the ether extract to 7.5 per cent.

74. *Hydrogen ion concentration of natural waters and the importance of its measurement.* (Lantern.) V. E. SHELFORD, University of Illinois and Illinois Natural History Survey.

A comparison of the midsummer hydrogen ion concentrations of various rivers of the United States and Canada which ranges from pH 6.4 to 8.6. Differences form a basis for easy selection of different streams and different tributaries by migrating fish. The relations of hydrogen ion concentration and "alkalinity" to survival and growth of animals in the presence of little oxygen and the sharp reaction of many animals will be urged as reasons for its determination.

75. *An analysis of the spawning habits of Chaetopleura apiculata.* (Say.) B. H. GRAVE, Wabash College.

1. *Chaetopleura* eggs are probably discharged in nature at the approach of full moon during the months of July and August and to some extent in June and September. The periodicity is not sharply marked although experiments in 1919 seemed to indicate a very distinct periodicity beginning two or three days before full moon and continuing for a week thereafter. No eggs were secured after that date until the near approach of the next full moon. Experimental results in 1920 are less clearly defined but warrant the above conclusion.

2. The sexual products are rarely shed in the day time. They usually begin about eight or nine p.m. and continue for several hours and, at the height of the season, throughout most of the night.

3. The spawning reflex is not induced by a chemical stimulus, as is the case in *Nereis*. Each sex will shed its products when isolated.

4. Laboratory experiments do not furnish reliable criteria for determining normal breeding habits. This is because animals are sensitive to unavoidable shock. It may be shown that oviposition may be induced in many animals by rough and unusual handling, examples of which are given in the text.

5. Periodicity in the shedding of the sexual products seems to be a much more common phenomenon than has formerly been suspected, and further study is likely to reveal this to be a fact. In cases so far studied, the periodicity is related in some way to the cycles of the moon and tides, or to effects upon the development of the sex cells produced by changes in the environment, due to these tidal changes. No adequate explanation of the phenomenon has been proposed but a number of suggestions have been made. Cf. Heppleman, Mayer, Scott, Lillie, Grave. The effects of light, temperature, and pressure have been proposed as effective stimuli. The conditions which surround these species are so varied that the same factors are not equally effective in all cases. It is likely, therefore, that no one explanation is applicable in all instances although the cause of periodicity must be fundamentally the same in all of them. Some kind of shock appears to be the immediate cause.

76. South America and its intercontinental land connections as indicated by a study of the geographic distribution of the Anura and their Opalinid parasites. M. M. METCALF.

A comparison of the geographical distribution of the species of Anura with that of the Anuran Opalinids gives indication of the following relations:—

1) Patagonia was once connected with Australia, doubtless by way of Antarctica, and at that time climatic conditions in Antarctica were favorable for Anuran life. 2) At this time, when Patagonia and Australia were united, Patagonia was not connected with tropical America. 3) When Patagonia lost its connection with Australia it established connection with tropical America. 4) At a period later than the establishment of connection between Patagonia and tropical America, the West Indian land was still united to tropical America. 5) At a period at least as late as this there was land connection between Siberia and Alaska and a mild climate suitable for Anura. 6) For at least two geologic periods there has been, as now, a bar to the migration of moist-skinned Anura (Ranids and Leptodactylids) across northern Mexico and south-western United States. 7) There are five lines of evidence from the Opalinids, but not conclusive, of a connection between Africa and tropical America (not including Patagonia). This land-bridge was not by way of Antarctica. If it existed it was earlier than Pliocene times, probably disappearing as early as early miocene.

77. Relation of temperature and tides to the quantity and distribution of oyster larvae. (Lantern.) E. P. CHURCHILL, University of South Dakota. *Read by permission of the United States Commissioner of Fisheries.*

During the Summer of 1919, studies on this subject were carried on for the United States Bureau of Fisheries, in Great South Bay, Long Island, by the author and Mr. J. S. Gutsell. Stations for observation were located in representative points in the Bay. Collections of the free-swimming oyster larvae were made at these stations every other

day, by pumping known quantities of water through a plankton net. The examination of the larvae was facilitated by straining the material through copper wire sieves of various sizes of mesh. The number, size and stage of development of the larvae in each sample were recorded together with data, relative to the temperature, tide, weather, etc., at the station where the collection had been made. About two hundred and fifty samples of water were taken during the oyster spawning season, which extended that year from about June 5th to July 17th. The spawning began about the time the water temperature reached 70 degrees Fahrenheit and proceeded briskly while it ranged from seventy to seventy-five but slowed down or ceased when the temperature fell to seventy-five or above. July 2nd to 6th, the bulk of the spawn was thrown out in the course of two or three days. The length of the free swimming period of the larvae was twelve to fourteen days.

The currents caused by the tide carried the larvae about in the Bay. The tidal movements were such as to cause the larvae to become concentrated in certain definite areas of the Bay. In general the larvae were most numerous at a point about half way out along the buoyed channel from West Sayville to Ocean Beach and diminished in numbers from this point each way to the ends of the channel. Beds of oyster shells, which had been placed in various parts of the Bay, were examined after July 17th for the presence of attached larvae or set. It was found that set was most abundant on the beds in the region where the larvae had been most numerous and that beds outside of the channel, where few larvae had been found, received a smaller amount of set and those at the ends of the Bay, two or three miles from the channel, received practically none at all.

78. Some reactions of the jelly-fish, Aequorea. A. O. Weese and M. T. Townsend.

Aequorea tends to select sea water with a pH of about 8.1, i.e., about the normal hydrogen ion concentration of Puget Sound sea water. When the animal encounters water with a pH lower than 6.8, it reacts by turning its oral surface up and actively moving downward and finally ceasing to pulsate. In water of constantly increasing pH pulsation ceases at a pH of about 8.9, but the avoiding reaction does not usually follow.

If the temperature is gradually raised the animals seek lower levels at about 20°C. A temperature as low as −2°C. did not prove fatal.

In water of gradually decreasing salinity Aequorea seeks a lower level at a point corresponding to 20 gms. of NaCl per liter or two-thirds the concentration of normal sea water.

79. Longevity of Trogoderma tarsale *larvae without food.* J. E. Wodsedalek, University of Idaho.

About three years ago the writer published the results of the first series of starvation experiments with Trogoderma tarsale larvae. In that case the last of a number of specimens lived, without a particle to eat, for a period of five years and two months. The larvae concerned

had undergone considerable disturbance occasioned by long trips on a train and variations in temperature which reduced their longevity.

In this second and more extensive series of experiments the larvae were undisturbed and lived at a fairly constant room temperature. Eight classes of specimens ranging from 1 to 8 mm. in length, each comprising ten individuals, were selected for starvation until death occurred. The larvae gradually decreased in size and practically all of them dwindled down to the hatching size of 1 mm. before dying. Two out of ten of the largest specimens lived over six years without food, the last one dying after six years, two months, and seven days of starvation.

In another experiment groups of specimens varying in size from 2 to 8 mm. in length are undergoing periods of "feasting and fasting." The larvae in various stages of starvation when given plenty of food again begin to grow in size. For example, some of the large specimens are on their way to their fourth 'childhood' after having attained the maximum larval size three times; while specimens originally 4 mm. in length are on their way to their ninth 'childhood' after reaching 4 mm. eight times. The status of various other phases of the problem will be briefly presented.

80. The problem of the local distribution of Thias lapillus imbricatus (*Lamarck.*) HAROLD S. COLTON, University of Pennsylvania.

The delicate imbricated variety of *Thais* (*Purpura*) lapillus forms a large element of the Thais population of the littoral formation of certain sheltered bays and harbors of the Coast of Maine and is nearly absent from other bays and harbors offering a similar environment. Although commonly absent from the rocks exposed to surf it has been found in proportions ranging from 17 per cent to 95 per cent on the exposed rocks of Duck Island and Grand Manan. This fact upsets the commonly accepted explanation of the distribution of Thais imbricatus, viz., that the delicate shells are destroyed by wave action on the exposed coast and natural selection is the important factor determining their presence or absence. Again, in two adjoining bays the correlation between the exposure to wave action and the proportion of imbricated forms is very different:—in one bay the correlation is almost perfect and in the adjoining bay nearly zero.

Whatever the factor is, which determines the distribution of the imbricated variety, an examination of 20,000 shells from 106 different stations proves that it is not wave action alone.

SYMPOSIUM OF FERTILIZATION

81. A critical discussion of the chromidial formation of nuclei, of autogamy, and of the multiple division of polyenergid nuclei, with especial reference to the unity of the mechanism of heredity in the Protozoa and Metazoa. CHARLES ATWOOD KOFOID. Univ. of California, Berkeley.

The fundamental unity of the mechanism of heredity in the Metazoa and Metaphyta as a whole is becoming increasingly evident. This includes the mitotic process, maturation, and fertilization with attendant synapsis and segregation and diploid and haploid stages of the nuclei of the organism. Attached to this conception of this mechanism as more or less essential corollaries are the current conclusions as to the individuality of chromosomes and their continuity from generation to generation, the particulate theory of inheritance, the localization of genes, and the phenomenon of crossover.

The primacy of the Protista in the evolutionary process leads us to turn to them for the developmental steps in the perfection of the hereditary mechanism. We find the evidence somewhat diversified as might be expected, and not a little chaotic. For example, if the de novo origin of nuclei of vegetative cells of gametes, and even of zygotes, occurs as described in Protozoa, the hereditary mechanism operates in the category of chromidial granules instead of in that of chromosomes and their localized parts. The chromidial hypothesis of Hertwig, as elaborated by Goldschmidt and the Schaudinn-Hartmann school, is based on the conception of a cytoplasmic idiochromatin of nuclear origin. These cytoplasmic inclusions in flagellates and rhizopods, especially in those of the digestive tract of vertebrates, are basophilic chromatoidal substances appearing in the cytoplasm during an acidophile phase of the nucleus. They are often associated, as they are in Arcella, with the coincident appearance of glycogen in the cytoplasm. I find no evidence that they ever as such form secondary nuclei, or that the primary nucleus disappears during their formation. The so-called secondary nuclei of supposedly chromidial origin are in reality derived as usual by mitosis. The evidence thus far presented of the de novo chromidial origin of protozoan nuclei is wholly inadequate to establish this hypothesis.

The occurrence of autogamy with attendant automixis in the Protozoa lacks thus far any conclusive evidence of synapsis or segregation and in no case is there a demonstration of the expected haploid—diploid sequence based on the accurate determination of the numbers of the chromosomes in the supposed periods of maturation and syngamy. In the autogamy of Actinosphaerium, as described by Hertwig, there is a significant resemblance to endomixis in Paramoecium and inadequate evidence of syngamy of the supposed pronuclei. The autogamy in Endamoeba coli of Schaudinn confuses the life-cycle of that species with phases of the yeast-like Blastocystis of human faeces. That described by Prowazek for Bodo is based on an analogous confusion, and that described by him for Trichomastix confuses in one cycle a flagellate and an amoeba. On the other hand, the autogamous cycle of the rhizomastigote flagellate described by Goldschmidt appears to involve a case of parasitism. Parasitism by the problematical organism Sphaerita may also easily give rise to appearances of the de novo origin of secondary nuclei in its host.

The multiple autogamy recently described in Endamoeba coli in Japan is a condition often seen in the cysts of this amoeba when recently divided nuclei are crowded within an encapsuling zone of chromatoidal material. It is possibly pathological or degenerative, but is certainly not autogamy.

The coincident multiple mitosis of so-called polyenergid nuclei in the Radiolaria, wherein one large nucleus breaks up into many small ones without mitosis, is under suspicion as a base of parasitism similar to that by Amoebophrya, or by a parasitic dinoflagellate. More conclusive evidence is needed to establish the normality of this phenomenon. We may therefore dismiss the chromidial origin of nuclei, chromidiogamy, autogamy, and multiple nuclear division in the Protozoa as without adequate cytological foundation.

82. The initial event in fertilization. FRANK R. LILLIE.

The initial event in fertilization has a primary significance because all others depend for their occurrence upon it and for their degree of efficiency upon its quantitative value. The initial event also displays a high degree of simplicity in relation to subsequent events.

Two new methods of study are applied in this paper to its study: first, the effect of copper salts upon the fertilization reaction; second, a comparison of the relative degrees of specificity between sperm agglutination by egg secretions and the fertilization reaction itself.

Copper has an incomparably greater effect on the initial reaction in fertilization than on later stages in Arbacia. It may therefore be used for an analysis of this reaction. The results indicate the presence of a copper-avid substance in the cortex of the egg that is responsible for activation.

The specificity of sperm agglutination by egg secretions between two species of Strongylocentratus is found to be of the same order as fertilization specificity.

The copper-avid substance of the cortex of the egg is to be identified with the sperm agglutinating substance of egg secretions and with the fertilizing of previous papers.

83. The susceptibility of the inseminated egg to hypotonic sea-water. A contribution to the analysis of the fertilization-reaction. E. E. JUST.

I

1. The uninseminated egg of Echinarachnius parma may be exposed to the action of hypotonic sea-water without loss of fertilization capacity. The length of this exposure depends upon the degree of dilution of the sea-water. Thus, eggs may be exposed to *full strength* tap-water for one to one and one half minutes and retain capacity for fertilization. On return to normal sea-water such eggs develop despite the abnormal behavior of the germ nuclei or their chromosomes which a study of sectioned material has revealed.

2. Immediately after insemination in sea-water and up to about forty seconds after insemination, eggs of Echinarachnius exposed to

the action of hypotonic sea-water develop on return to normal sea-water. As in the case of the uninseminated egg, the per cent of cleavage and of larvae as well as the normality of development depends upon the length of time the eggs have remained in the hypotonic sea-water and upon the degree of dilution employed.

3. Eggs two minutes after insemination are likewise resistant to the action of hypotonic sea-water as measured by the per cent and quality of development on return to normal sea-water. In these three stages, the eggs, as so far measured, are about equally resistant to a given dilution of sea-water. After two minutes following insemination, however, the egg increases in resistance to hypotonic treatment. Ten to fifteen minutes after insemination, for example, the egg is most resistant.

4. With eggs exposed to hypotonic sea-water forty to one hundred twenty seconds after insemination, the case is quite different. During this period of about eighty seconds the eggs are highly susceptible to the action of dilute sea-water. Thus, eggs exposed to *full strength* tap-water forty seconds after insemination show one hundred per cent disintegrated in fifteen seconds or less; whereas the uninseminated egg does not disintegrate in tap-water under two minutes. The susceptible period is thus sharply defined.

II

1. The period of susceptibility to hypotonic sea-water exhibited by inseminated Echinarachnius eggs runs parallel with the separation of the so-called fertilization membrane through the break-down of the cortex of the egg. If eggs are exposed to hypotonic sea-water at the moment of membrane separation they cytolyze rapidly. With complete membrane separation the period of susceptibility ends; the egg is again resistant.

Eggs exposed to dilute sea-water during the period of membrane separation cytolyze by bursting at that point where the membrane was lifting at the moment of exposure. Thus, if the membrane is off just above the point of sperm entry, where membrane separation begins, the cytoplasm breaks down at this point; if the membrane is one half off, the break-down takes place in the angle between the separated membrane and the egg; and if the membrane is lifting from its lats point of attachment to the egg (the pole opposite to that of sperm entry) the break-down is at this point. All zones of the cortex from which the membrane has lifted are resistant; likewise, are those to which the membrane is still stuck. The susceptibility of the egg is, therefore, clearly due to weakness of the cortex only in that zone from which the membrane is lifting.

2. Can this low resistance to hypotonic sea-water be an osmotic phenomenon? What is the rôle of the so-called fertilization membrane during this period? How does this period of low resistance compare with that just before cleavage? What are the physical properties of the egg substance at this time? May we compare the wave of susceptibility sweeping around the egg with other forms of protoplasmic

transmission? These are but a few of the questions that this study raises and attempts to answer. By far the most important question at this time, however, is this: how does this period of susceptibility relate itself to the fertilization-reaction?

III

1. The increase in susceptibility of the inseminated egg to hypotonic sea-water is not the cause of fertilization; nor is it the fertilization-reaction itself.

A. The egg is fertilized before the membrane lifts. (1) A mass of data shows that inseminated eggs exposed to hypotonic sea-water prior to membrane separation are capable of developing. (But this, however, is also true of the uninseminated egg.) (2) Polyspermy is blocked before membrane separation begins. (3) Other visible cortical changes precede those leading to membrane separation. (4) The case of Platynereis shows us how rapidly sperm may effect profound changes in the egg.

B. That the susceptibility of the inseminated Echinarachnius egg is purely a cortical (local) phenomenon and not the fertilization-reaction is supported by observations of the susceptibility of Arbacia and Nereis eggs to hypotonic sea-water.

2. It is therefore held as hitherto that the fertilization reaction is practically an instantaneous reaction between sperm and an ovogenous substance, fertilizin.

84. Fertilization and egg-secretions. Otto Glaser, Amherst College.

1. Egg secretions have been known for some time from the eggs of at least ten species of echinoderms, two of annelids, two of tunicates, and one of molluscs. To this list I now add another mollusc, the oyster, and two vertebrates, the fish, Fundulus heteroclitus, and the frog, Rana pipiens.

2. The importance of these secretions in the initiation of development has been demonstrated by a variety of methods. One of these, that of washing the eggs, has been criticized because in the eighteen to thirty-six hours required to remove all traces of their exudates, the eggs themselves may undergo serious deteriorations of other sorts. By using running sea water, I have been able to shorten this period to three or four hours, and by removing their jelly and exposing the eggs to charcoal, I have succeeded in sterilizing them completely in thirty minutes.

3. The secretions agglutinate spermatozoa and initiate development. These effects are due, not to one substance with two side-chains, as postulated in the Fertilizin Theory, but to two chemical entities, the lipolysin on the one hand, and the agglutinin, on the other.

4. The lipolysin is a lipolytic ferment and catalyses the hydrolysis of the esters of the lower as well as the higher fatty acids. It may be that more than one ferment is involved.

5. The agglutinin very possibly is also a ferment, but the process which it catalyses has not yet been found.

6. A study of the specificities of fertilization must take account of the lipolysin and of the agglutinin. With respect to the former, it is possible to employ lipolysins derived from the eggs of arbacia, asterias, and of the oyster, for the purpose of increasing the fertility of Echinarachnius eggs partially sterilized by the removal of their own secretions; With respect to the agglutinin, it is possible to increase very greatly the success of crosses between Echinarachnius parma and Arbacia punctulata, if one kind or the other of their sex cells, but especially the spermatozoa, are treated with species-true egg secretion prior to insemination. It appears therefore that the agglutination reaction involves specific features because species-true agglutinin has effects quantitatively and perhaps qualitatively different from those of heterogeneous agglutinins.

Whatever transformations our views on the initiation of development may undergo within the next few years, the zone within which we must seek for understanding is now marked off by the reaction capacities of perfectly definite physiological compounds.

85. The chromosomes in fertilization. C. E. McClung.

1. The process of fertilization consists essentially in the introduction into the egg of a simplex series of chromosomes, duplicating the series left there by oögenesis. Little or no other material is carried by the spermatozoön.

2. Since genetic experiments indicate the equivalence of male and female in heredity, the importance of the chromatin is demonstrated.

3. Behavior of characters in inheritance, indicating factor differences and groupings, are paralleled by conditions of structure and behavior of the chromosomes.

4. The chromosomes introduced by the spermatozoön are reduced to the smallest volume and contain chromatin in the most condensed condition.

5. This chromatin quickly absorbs fluid from the egg cytoplasm and forms a nuclear vesicle in which the chromosomes later appear in the size, form, and number that marked them in the spermatid.

6. Upon union of the egg and sperm pronuclei the paternal chromosomes may remain distinctly grouped and this segregation may be followed through many generations of cells.

7. The individual paternal chromosomes may be traced into the body cells of the embryo and are found later in the germ cells.

8. During the many generations between the ovum and the adult organism in which maturation occurs, the chromosomes have reproduced themselves, each time under different conditions in the organization and constitution of the body, so that in the germ cells they must emerge somewhat different in character from what they were on entering.

9. At the period of maturation in the germ cells, however, the homologous elements from the two parents unite together in the most inti-

mate manner but without the loss of their individual identity, thus completing the process of union inaugurated by fertilization.

10. Still, distinguished by characteristics of form, size, and behavior, they are then segregated by chance and distributed again into mature germ cells in a simplex series. Through these they may be traced again into another generation of organisms where they repeat the series of processes.

11. Fertilization, although not necessary to reproduction, and omitted in parthenogenesis, is required in biparental inheritance and there serves the essential purpose of introducing the necessary duplicate control factors—the chromosomes.

86. Chromatic Material in Hybridization. David H. Tennent. Bryn Mawr College, Bryn Mawr, Pa.

Closeness of relationship is by no means indicative of the readiness with which the initial impulse to development may be received, nor a sure criterion of the extent to which it may proceed. Some species hybridize in nature; some eggs show a cortical block which may be removed readily by various methods. The entrance of a spermatozoan following the removal of the cortical block, may result in development, or it may result in an instantaneous, or in a slower but none the less complete cytolysis of the egg.

In some crosses, in which a specialized type of development is superimposed on a more general type, development proceeds regularly up to the point of deviation of special from general. Internal block may become effective apparently at any stage after the entrance of the spermatozoan. Many degrees of inhibition, ranging from failure of the germ nuclei to unite to failure of synapsis have been described, but no methods of overcoming its effects have been devised.

From our knowledge of straight fertilization and of cross fertilization we have come to look upon development as an attribute of the egg. In eggs of Arbacia fertilized by sperms of Moira, an interordinal cross, a rhythmic appearance of basophilic bodies in the cytoplasm may be seen. A similar phenomenon has been described in many species fertilized eggs. By the application of binuclearity hypotheses, founded in part on the chromidial hypothesis, to the metazoan cell, these basophilic bodies have been explained as somatochromatin or trophochromatin. The evidence for the emission of chromatin as such from the nucleus is not convincing. In the conditions of the experiment mentioned, a foreign enzyme was introduced. Its presence produced a coalescence of granules into coarsely dispersed aggregates. It is suggested that this coalescence is a result of dehydration due to the activity of the foreign enzyme in the cytoplasm. These bodies are regarded as synthesized in the cytoplasm. We cannot hope to distinguish between more than very widely spaced steps in synthesis within the cell by methods of staining. The egg and spermatozoan may form a harmonious system, the degree of harmony being a function of cytoplasmic substrate and nuclear enzyme.

PAPERS RECEIVED TOO LATE TO CLASSIFY

88. A new method of ingestion—exemplified in the ciliate Frontonia. William M. Goldsmith, Southwestern College. (Introduced by S. O. Mast.)

Observations and experimentations were made upon the Ciliate Frontonia while these organisms were ingesting, not only their favorite food—Euglena, diatoms, desmids, and Oscillatoria, but also silk and cotton fibers and various other foreign materials. The ingestion of blue-green algae, which produced fantastic figures through the contortion of the organism by the variously colored food, furnished the most conclusive demonstrations of the method involved, as the process continued a greater length of time and involved more factors. 1. The cilia of the cyto-pharynx exert a direct pull upon the incoming food. 2. The locomotory cilia drive the organism forward and thus force the food into the mouth. 3. The end of the fiber enters the mouth and passes antero-dorsally, after which the Frontonia swings around through an angle of 180 degrees, using the mouth as a pivot, thus permitting the fiber to pass down the dorsal side and to exert a pressure on the body wall at the extreme posterior end. Such points of contact are known as tension points, as a play of the three factors heretofore considered tends only to push the fiber through the body wall. 4. A series of short contractions of the body wall assists in relieving the tension point. 5. Cyclosis aids by moving the end of the fiber around the wall, thus forming a spiral and making further ingestion possible.

89. Copper: its occurrence and rôle in insects and other animals. Richard A. Muttkowski. (Introduced by J. E. Wodsedalek.)

During investigations on the respiration of insects the writer incinerated both the blood and entire specimens of over 40 species of insects, representing thirteen of the orders. These were selected to represent the greatest variety of stages, habitats, and food habits. The ash was analyzed for copper, on the supposition that the copper serves as the nucleus of a respiratory protein, hemocyanin. The amount found in all cases was nearly equal to that of the control substance, crayfish blood.

In addition to insects and crayfish, plankton Crustacea, spiders, centipeds, and other Arthropods were incinerated for copper, with positive results. To see how widely copper was distributed in the animal world the writer incinerated Volvox, Ascaris, Lumbricus, snails, slugs, mice, human and snake blood, with positive results in each case, except human blood.

For the sources of this copper the water, soil, and plants were tested. All three showed copper in varying amounts.

These results indicate that the element copper has a wider distribution in living organisms than heretofore accepted. Its function has been definitely ascertained for mollusks and a few Arthropods, where it forms the nucleus of a respiratory protein, hemocyanin. Its rôle in

other Arthropods is probably identical. For the amount of copper present in the various Arthropods incinerated was nearly equal to or exceeded that of the control substance, crayfish blood.

The copper ion is probably inactive in plants. It is known to be highly toxic to lower plants. Yet even these (Penicillium) contained copper.

90. The post-embryonic development of the compound eye of Drosophila melanogaster. JOSEPH KRAFKA, JR., University of Georgia. (Introduced by Charles Zeleny.)

A histological study has been made of the development of the compound eye of Drosophila melanogaster Meig. The embryoblasts are present at the time of hatching, although the ommatidia are not completely metamorphosed until the late pupal period. The segmented condition of the optic ganglion, before definitive visual structures appear, suggests that the formation of the latter may be under the control of the nervous system. A marked reduction in the size of the optic ganglion in the bar-eyed mutant shows that the hereditary factor involves more than the facet-number.

91. The sex element in the flash of the firefly. C. R. FOUNTAIN, Mercer University.

While engaged in researches as to the nature of the chemical reactions in the firefly which cause the flash of light, I had trouble during the latter part of the evening in catching as many fireflies as I needed in my researches. I hit upon the following method which I thought would be of some interest to the Zoologists, in view of the many discussions about the synchronous nature of the flashes.

Late in the evening the male fireflies are nearly all up in the tops of the trees and have ceased to flash. By means of a small flashlight held between my fingers I imitated the flash of the male firefly. Instantly there would be a number of responses from the grass, sometimes from a distance as great as 100 yards. Walking toward the nearest one I would flash several times, getting a response every time until I was within five feet, when apparently I was recognized as an imposter. However, I was always able from that distance to find the firefly by the faint continuous glow, or by the light of the flashlight itself. By this means I invariably found the female. In the early evening those flashing as they rise are mostly the males, at least 15 times as many males as females can be caught.

I might state that my observations seemed to prove that the chemical process is a slow oxidation, but I have not yet learned the exact type of chemical reaction that gives off this very efficient radiation. I am much more hopeful of finding out this now than when I first began the work.

AMERICAN SOCIETY OF ZOÖLOGISTS

CONSTITUTION, OFFICERS AND LIST OF MEMBERS OF THE SOCIETY

CONSTITUTION

ARTICLE I

NAME AND OBJECT

Section 1. The Society shall be called the "American Society of Zoölogists."

Sec. 2. The object of the Society shall be the association of workers in the field of Zoölogy for the presentation and discussion of new or important facts and problems in that science and for the adoption of such measures as shall tend to the advancement of zoölogical investigation in this country.

ARTICLE II

MEMBERSHIP

Section 1. Members of the Society shall be elected from persons who are active workers in the field of Zoölogy and who have contributed to the advancement of that science.

Sec. 2. Election to membership in the Society shall be upon recommendation of the Executive Committee.

Sec. 3. Each member shall pay to the Treasurer an annual assessment as determined by the Society. This assessment shall be considered due at the annual meeting and the name of any member two years in arrears for annual assessments shall be erased from the list of members of the Society, and no such person shall be restored to membership unless his arrearages shall have been paid or he shall have been re-elected.

Sec. 4. Foreign Zoölogists, not members of this Society, may be elected Honorary Fellows upon unanimous recommendation of the Executive Committee by a majority vote of the members present at any meeting of the Society. Honorary Fellows shall not be required to pay dues.

ARTICLE III

OFFICERS

Section 1. The officers of the Society shall be a President, a Vice-President a Secretary-Treasurer and the members at large of the Executive Committee.

Sec. 2. The Executive Committee shall consist of the President, the Vice President, the Secretary-Treasurer and five members elected from the Society at large. Of these five members, one shall be elected each year to serve five years. If any member at large shall be elected to any other office, a member at large shall be elected at once to serve out the remainder of his term.

Sec. 3. These officers shall be elected by ballot at the annual meeting of the Society and their official terms shall commence with the close of the annual

meeting, except that the Secretary-Treasurer shall be elected triennially and shall serve for three years.

Sec. 4. The officers named in Section 1 shall discharge the duties usually assigned to their respective offices.

Sec. 5. Vacancies in the board of officers, occurring from any cause, may be filled by election by ballot at any meeting of the Society. A vacancy in the Secretary-Treasurership occurring in the interval of the meetings of the Society may be filled by appointment, until the next annual meeting, by the Executive Committee.

Sec. 6. At the annual meeting the President shall name a nominating committee of three members. This committee shall make its nominations to the Secretary not less than one month before the next annual meeting. It shall be the duty of the Secretary to mail the list of nominations to all members of the Society at least two weeks before the annual meeting. Additional nominations for any office may be made in writing to the Secretary by any five members at any time previous to balloting.

Article IV

MEETINGS OF THE SOCIETY

Section 1. Unless previously determined by the Society the time and place of the annual meeting of the Society shall be determined by its Executive Committee. Special meetings may be called and arranged for by the Executive Committee. Notices of such meetings shall be mailed to all members of the Society at least two weeks before the date set for the meeting.

Sec. 2. Sections of the Society may be organized in any locality by not less than ten members, for the purpose of holding meetings for the presentation of scientific papers. Such sections shall have the right to elect their own officers and also associate members; provided, however, that associate membership in any section shall not confer membership in the Society.

Article V

QUORUM

Twenty-five members shall constitute a quorum of the Society and four a quorum of its Executive Committee.

Article VI

CHANGES IN THE CONSTITUTION

Amendments to this Constitution may be adopted at any meeting of the Society by a two-thirds vote of the members present, upon the following conditions:

(a) The proposed amendment must be in writing and signed by at least five members of the Society.

(b) This signed proposal must be in the hands of the Secretary at least one month before the meeting of the Society at which it is to be considered.

(c) The Secretary shall mail copies of the proposed amendment to the members of the Society at least two weeks before the meeting.

BY-LAWS

DUES

(1) The annual dues for members, unless remitted or changed by the vote of the Society, shall be seven dollars.

SECRETARY-TREASURER

(2) The duties and privileges of the Secretary-Treasurer shall be as follows:

(a) He shall keep the records and be in charge of the funds of the Society.

(b) At the annual business meeting he shall present a statement to date of the funds of the Society.

(c) Whenever the proper officers of a number of related societies shall have a conference with a view to determining a common time and place for the several annual metings, he shall act as the delegate or representative of this Society. (See also 5-a.)

(d) He shall employ a typewriter or printer whenever in his judgment such employment will expedite the business of the Society, and

(e) He shall be reimbursed out of the funds of the Society for expenses incurred in attending meetings of the Society.

AUDITING COMMITTEE

(3) The President shall annually appoint an auditing committee of two, who shall audit and report upon the financial record and statement of the Secretary-Treasurer at the meeting for which they were appointed.

(4) The National Research Council allows the Society three representatives on the Division of Biology and Agriculture. Of these three representatives, one shall be elected each year to serve three years. The method of election shall be the same as that used in the election of the officers of the Society.

AFFILIATION WITH THE AMERICAN SOCIETY OF NATURALISTS

(5) It shall be the policy of the Society to hold meetings in both Eastern and Central-Western territory, and the distribution of the meetings between the two territories shall be determined in general on the basis of the representation of Eastern and Western members in the Society. See also 2-e

PROGRAM RULES

(6) In matters relating to programs for annual meetings the following rules shall be observed:

(a) Papers shall be listed and presented according to subject matter in the following groups: 1. Comparative Anatomy; 2. Embryology; 3. Cytology; 4. Genetics; 5. Comparative and General Physiology; 6. Ecology, and 7. Miscellaneous, or other groups at the discretion of the Secretary-Treasurer.

(b) Whenever conditions require it the Executive Committee shall schedule two or more groups for the same hour and rearrange the program to bring together papers on subjects of more general interest for meetings of the whole Society. The Committee, however, is instructed to avoid conflicts as much as possible.

(c) Papers shall be listed in their respective groups in the order received. When a member offers more than one paper those following the one designated first shall be placed at the end of the list and shall not be read until all first papers by members shall have been twice called for.

(d) All papers not read when called for as listed shall be placed at the end of the group list, and, if not read when called for the second time, they shall be read by title only.

(e) The titles of "introduced" papers shall be listed in the groups after the titles of papers to be read by members. Such papers shall be read by title only in case the entire program cannot be completed during four regular sessions for reading papers.

(f) Fifteen minutes shall be the maximum time allowed for the presentation of a paper.

(g) Abstracts of papers for publication in the proceedings of the Society must be handed to the Secretary-Treasurer or his representative before final adjournment of the annual meeting.

HISTORICAL REVIEW

A review of the historical antecedents of the present American Society of Zoölogists will be found in *The Anatomical Record* for January, 1917. The list of officers and meeting places of the present Society found in the same place is brought up to date and reprinted here.

OFFICERS AND LIST OF MEMBERS[1]

American Society of Zoölogists (Amalgamated)

MEETING PLACES

1914—Philadelphia	1917—Minneapolis	1919—St. Louis
1915—Columbus	1918—Baltimore	1920—Chicago
1916—New York		

Officers for 1920

President	Gilman A. Drew
Vice-President	Caswell Grave
Secretary-Treasurer	W. C. Allee

Executive Committee

	Term expires
R. P. Bigelow	1920
H. V. Wilson	1921
M. M. Metcalf	1922
George Lefevre	1923
C. M. Child	1924

Representatives of the Society in the Division of Biology and Agriculture of the National Research Council

	Term expires
F. R. Lillie	1923
M. F. Guyer	1921
G. H. Parker	1922

EDITORIAL BOARD OF THE JOURNAL OF MORPHOLOGY

Managing Editor (Term expires 1926) ..... C. E. McClung

Associate Editors

To serve until 1922	Gary N. Calkins J. S. Kingsley William Patten
To serve until 1923	E. G. Conklin M. F. Guyer W. M. Wheeler
To serve until 1924	C. A. Kofoid F. R. Lillie J. T. Patterson

[1] The data given in this list is based on the last preceding list published in *The Anatomical Record*, Vol. 17, No. 5, with such corrections and additions as have come to the attention of the Secretary. Please notify the Secretary of errors in this copy of the membership list that they may be corrected in the next published list.

HONORARY MEMBER

JAMES VISCOUNT BRYCE, HINDLEAP, FOREST ROW, SUSSEX, ENGLAND

LIFE MEMBERS

ANDREWS, ETHAN ALLEN, Ph.B. (Yale), Ph.D. (Johns Hopkins), Professor of Zoölogy, *Johns Hopkins University, Baltimore, Md.*

DEAN BASHFORD, A.B. (College of City of New York), A.M., Ph.D. (Columbia), Professor of Vertebrate Zoölogy, Columbia University; Curator Emeritus of Fishes and Reptiles, *American Museum Natural History, Riverdale-on-Hudson, New York.*

HENSHAW, SAMUEL, Director of Museum of Comparative Zoölogy, *8 Fayerweather Street, Cambridge, Mass.*

MAYER, ALFRED GOLDSBOROUGH, M.E. (Stevens Inst. Tech.), Sc.D. (Harvard), Director Department Marine Biology, Carnegie Institution of Washington, *276 Nassau Street, Princeton, N. J.*

METCALF, MAYNARD MAYO, A.B., Sc.D. (Oberlin), Ph.D. (Johns Hopkins), Orchard Laboratory, *128 Forest Street, Oberlin, Ohio.*

MOORE, J. PERCY, Ph.D. (Pennsylvania), Professor of Zoölogy, *University of Pennsylvania, Philadelphia, Pa.*

STILES, CHARLES W., A.M., Ph.D. (Leipzig), S.M., S.D. (Wesleyan), Professor of Zoölogy, United States Public Health and Marine Hospital Service, Hygienic Laboratory. *Twenty-fifth and E Streets, N.W., Washington, D. C.* (October 1–May 1); *Wilmington, N. C.* (May–October 1).

MEMBERS

ACKERT, JAMES EDWARD, A.B., A.M., Ph.D. (University of Illinois), Professor of Zoölogy, Parasitologist Agr. Exp. Station; *Kansas State Agricultural College, Manhattan, Kan.*

ALLEE, WARDER CLYDE, S.B. (Earlham College), S.M., Ph.D. (Chicago), Professor of Biology, Lake Forest College, *Lake Forest, Ill.*

ALLEN, BENNET MILLS, Ph.B. (DePauw), Ph.D. (Chicago), Professor of Zoölogy, *University of Kansas, Lawrence, Kan.*

ALLEN, EZRA, A.B., A.M. (Bucknell), Ph.D. (University of Pennsylvania), Professor of Biology, *Ursinus College, Collegeville, Pa.*

AREY, LESLIE BRAINERD, Ph.D. (Harvard), Professor of Microscopic Anatomy, *Northwestern University Medical School, 2431 Dearborn St., Chicago, Ill.*

BAITSELL, GEORGE ALFRED, B.S. (Central College, Iowa), M.A., Ph.D. (Yale), Assistant Professor of Biology, Yale University, *Osborn Zoölogical Laboratory, Yale Station, New Haven, Conn.*

BAKER, ARTHUR CHALDEN, B.S.A. (Toronto University), Ph.D. (George Washington University), Entomological Assistant, *Bureau of Entomology, Washington, D. C.*

BANTA, ARTHUR MANGUN, A.B., A.M. (Indiana), Ph.D. (Harvard), Resident Investigator, *Station for Experimental Evolution, Carnegie Institution, Cold Spring Harbor, Long Island, N. Y.*

BARROWS, WILLIAM MARTIN, B.S. (Michigan Agricultural College), S.B., S.M. (in biology) (Harvard), Department of Zoölogy and Entomology, *Ohio State University, Columbus, Ohio.*

BARTELMETZ, GEORGE W., Ph.D. (Chicago), Associate Professor of Anatomy, *University of Chicago, Chicago, Ill.*

BAUMGARTNER, WILLIAM JACOB, A.B., A.M. (Kansas), Associate Professor of Zoölogy, *University of Kansas, 1209 Ohio Street, Lawrence, Kan.*

BECKWITH, CORA JIPSON, B.S. (Michigan), M.A., Ph.D. (Columbia), Associate Professor of Zoölogy, *Vassar College, Poughkeepsie, N. Y.*

BELLAMY, ALBERT W., Ph.D. (Chicago), Instructor in Zoölogy, *University of Chicago, Chicago, Ill.*

BIGELOW, MAURICE ALPHEUS, B.S. (Ohio Wesleyan), M.S. (Northwestern), Ph.D. (Harvard), Professor of Biology, Teachers College, *525 West 120th Street, New York City.*

BIGELOW, ROBERT PAYNE, S.B. (Harvard), Ph.D. (Johns Hopkins), Associate Professor of Zoölogy and Parasitology, *Massachusetts Institute of Technology, Cambridge, Mass.*

BINFORD, RAYMOND, B.S. (Earlham), S.M. (Chicago), Ph.D. (Johns Hopkins), President of Guilford College, *Guilford, N. C.*

BOECK, WILLIAM CHARLES, B.S., M.A., Ph.D., Hygiene Laboratory, U. S. Public Health Service, Washington, D. C.

BORING, ALICE MIDDLETON, A.B., A.M., Ph.D. (Bryn Mawr), *Wellesley College, Wellesley, Mass.*

BOYDEN, E. A., Ph.D. (Harvard), Assistant Professor Comparative Anatomy, *Harvard Medical School, 61 Clark Street, Newton Center, Mass.*

BRUNER, HENRY LANE, A.B. (Abingdon), Ph.D. (Freiburg), Professor of Biology, *Butler College, 324 South Ritter Avenue, Indianapolis, Indiana.*

BUDINGTON, ROBERT ALLYN, B.A., M.A. (Williams), Professor of Zoölogy, *Oberlin College, Oberlin, Ohio.*

BURROWS, MONTROSE T., A.B. (Kansas), M.D. (Johns Hopkins), *Washington University Medical School, St. Louis, Mo.*

BYRNES, ESTHER F., Ph.D. (Bryn Mawr), *193 Jefferson Avenue, Brooklyn, N.Y.*

CALKINS, GARY N., B.S. (Mass. Inst. Tech.), Ph.D. (Columbia), Professor of Protozoölogy, *Columbia University, New York City.*

CALVERT, PHILIP POWELL, Ph.D. (Pennsylvania), Professor of Zoölogy, *University of Pennsylvania, Zoölogical Laboratory, Philadelphia, Pa.*

CAROTHERS, E. ELEANOR, A.B., A.M., Ph.D., *Zoölogical Building, University of Pennsylvania, Philadelphia, Pa.*

CARPENTER, FREDERIC WALTON, B.S. (New York University), A.M. Ph.D. (Harvard), Professor of Biology, *Trinity College, Hartford, Conn.*

CARY, LEWIS R., B.S., M.S (Maine), M.A., Ph.D. (Princeton), Assistant Professor of Biology, *Princeton University, Princeton, N. J.*

CASTEEL, DANA BRACKENRIDGE, A.B. (Allegheny), A.M. (Ohio Wesleyan), Ph.D. (University of Pennsylvania), Associate Professor of Zoölogy, *University of Texas, Austin, Texas.*

CASTLE, WILLIAM E., A.B. (Denison), A.M., Ph.D. (Harvard), Professor of Zoölogy in *Harvard University, Payson Road, Belmont, Mass.*

Chambers, Robert, Jr., M.A. (Queen's University, Can.), Ph.D. (Munich), Assistant Professor in Anatomy, *Cornell University Medical College, 28th Street and First Avenue, New York City.*

EDMONDSON, CHARLES HOWARD, Ph.B., M.S., Ph.D. (Iowa University), Professor of Zoölogy, Director of Research Laboratory, *College of Hawaii, Honolulu.*

EDWARDS, CHARLES LINCOLN, B.S. (Lombard and Indiana), A.M. (Indiana), Ph.D. (University of Leipzig), Director, Department of Nature Study, Los Angeles City Schools, *1032 West 39th Place, Los Angeles, Calif.*

EIGENMANN, CARL H., A.B., A.M., Ph.D. (Indiana), Research Professor and Dean of the Graduate School, *Indiana University, Bloomington, Ind.*

ENDERS, HOWARD EDWIN, B.S. (Lebanon Valley College), B.S., M.S. (Michigan), Ph.D. (Johns Hopkins), Associate Professor of Zoölogy and in charge of Biology, Purdue University; Summer School Staff, Dept. Zöology, Indiana University, *107 Fowler Ave., West Lafayette, Indiana.*

ERDMANN, RHODA, Ph.D. (Munich), Berlin-Wilmersdorf, Nassauische str. 17[II], Germany.

ESTERLY, CALVIN O., A.B., A.M. (California), Ph.D. (Harvard), Zoölogist, Scripps Institution, La Jolla, California; Professor of Biology, *Occidental College, Los Angeles, Calif.*

FASTEN, NATHAN, B.S. (College of City of New York), Ph.D. (Wisconsin), Associate Professor of Zoölogy, *Oregon Agricultural College, Corvallis, Ore.*

FERRIS, HARRY BURR, B.A., M.D. (Yale), E. K. Hunt Professor of Anatomy, Medical Department, Yale University, *395 St. Ronan, New Haven, Conn.*

FOX, HENRY, B.S., M.A., Ph.D. (University of Pennsylvania), Professor of Biology, *Mercer University, Macon, Ga.*

FRASER, CHARLES MCLEAN, A.B., A.M. (Toronto), Ph.D. (Iowa), Professor of Zoology, University of British Columbia and Director of Marine Biological Station, Nanaimo, *University of B. C., Vancouver, B. C., or Biological Station, Nanaimo, B. C.*

GAGE, SIMON HENRY, B.S. (Cornell), Emeritus Professor of Histology and Embryology, *Cornell University, Simson Hall, Ithaca, N. Y.*

GALLOWAY, THOMAS W., A.B., A.M., Ph.D. (Cumberland), A.M. (Harvard), Litt.D. (Missouri Valley), *105 W. 40th St., New York City.*

GARMAN, HARRISON, D.Sc. (Kentucky), Professor of Entomology and Zoölogy, Kentucky Agricultural Experiment Station; State Entomologist, *Lexington, Ky.*

GEE, WILSON, B.S. (Clemson), M.A. (University of South Carolina), Ph.D. (University of California), *University of South Carolina, Columbia, S. C.*

GEROULD, JOHN H., Litt.B. (Dartmouth), A.B., A.M., Ph.D. (Harvard), Professor of Biology, Dartmouth College, *36 Occom Ridge, Hanover, N. H.*

GLASER, OTTO CHARLES, A.B., Ph.D. (Johns Hopkins), Professor of Biology, *Amherst College, Amherst, Mass.*

GOLDFARB, A. J., B.S. (College of City of New York), Ph.D. (Columbia), Professor of Biology, College of City of New York, *Convent Ave., New York City.*

GOLDSCHMIDT, RICHARD B., Ph.D. (Heidelberg), Kaiser Wilhelm Institut für Biologie, *Berlin-Lichterfelde 3, Germany.*

GOLDSMITH, WILLIAM MARION, B.Pd., A.B., A.M., Ph.D. (Indiana), Professor of Biology, Southwestern College, *Winfield, Kansas.*

GOODALE, HUBERT DANA, Ph.D. (Columbia), Research Biologist, *Massachusetts Agricultural Experiment Station, North Amherst, Mass.*

GOODRICH, HUBERT BAKER, B.S. (Amherst), M.A., Ph.D. (Columbia), Instructor in Zoölogy, *Wesleyan University, Middletown, Conn.*

GRAHAM, JOHN YOUNG, Ph.D. (Munich), Professor of Biology, *University of Alabama, University, Ala.*

GRAVE, BENJAMIN H., B.S., (Earlham) M.S. (Carleton), Ph.D. (Johns Hopkins), Professor of Zoölogy, *Wabash College, Crawfordsville, Ind.*

GRAVE, CASWELL, B.S. (Earlham), Ph.D. (Johns Hopkins), Professor of Zoölogy, *Washington University, St. Louis, Mo.*

GREGORY, LOUISE H., A.B. (Vassar), A.M. Ph.D. (Columbia), Instructor in Zoölogy, *Barnard College, New York City.*

GRIER, NORMAN MCDOWELL, S.B., A.M., Ph.D. (Pittsburgh), Professor of Biology, Washington and Jefferson College, *Washington, Pa.*

GRIFFIN, LAWRENCE EDMONDS, A.B., Ph.B. (Hamline), Ph.D. (Johns Hopkins), Reed College, Portland, Oregon.

GROSS, ALFRED O., A.B. (Illinois), Ph.D. (Harvard), Assistant Professor of Zoölogy, *Bowdoin College, Brunswick, Maine.*

GUBERLET, J. E., A.M., Ph.D. (Illinois), Parasitologist, Oklahoma A. and M. College, *Stillwater, Okla.*

GUDGER, E. W., B.S., M.S. (Nashville), Ph.D. (Johns Hopkins), *American Museum of Natural History, New York City.*

GULICK, ADDISON, A.B. (Oberlin), A.M. (Harvard), Ph.D. (Wurzburg, Germany), Assistant Professor in Physiology, University of Missouri, *903 Lake Street, Columbia, Mo.*

GUYER, MICHAEL F., B.S. (Chicago), A.M. (Nebraska), Ph.D. (Chicago), Professor of Zoölogy, *University of Wisconsin, Madison, Wis.*

HALL, MAURICE CROWTHER, S.B. (Colorado), M.A. (Nebraska), Ph.D. (George Washington), D.V.M. (George Washington), Senior Zoölogist, Zoölogical Division, *Bureau of Animal Industry, Washington, D. C.*

HAMAKER, JOHN IRVIN, A.B. (Kansas), A.B., A.M., Ph.D. (Harvard), Professor of Biology, Randolph-Macon Woman's College, *12 Princeton Street, Lynchburg, Va.*

HANCE, R. T., A.B., M.A., Ph.D. (Pennsylvania), Instructor in Zoölogy, University of Pennsylvania, *Zoölogical Laboratory, University of Pennsylvania, Philadelphia, Pa.*

HANSON, FRANK BLAIR, A.B. (George Washington), A.M. (Illinois), Ph.D. (American University), Assistant Professor of Zoölogy, Washington University, *Department of Zoölogy, Washington University, St. Louis, Mo.*

HARGITT, CHARLES W., Ph.D. (Ohio University), Professor of Zoölogy, Director of Laboratories, *Syracuse University, Syracuse, N. Y.*

HARGITT, GEORGE THOMAS, Ph.B. (Syracuse), A.M. (Nebraska), Ph.D. (Harvard), Associate Professor of Zoölogy, *Syracuse University, 909 Walnut Ave., Syracuse, N. Y.*

HARMON, MARY THERESA, A.B., M.A., Ph.D. (Indiana), Assistant Professor of Zoölogy, *Kansas State Agricultural College, Manhattan, Kan.*

HARPER, EUGENE HOWARD, A.B. (Oberlin), A.M. (Harvard), Ph.D. (Chicago), *Bedford, Va.*

HARRISON, ROSS GRANVILLE, Ph.D. (Johns Hopkins), M.D. (Bonn), Bronson Professor of Comparative Anatomy, Yale University, *142 Huntington St., New Haven, Conn.*

HARTMAN, CARL G., Ph.D. (Texas), Associate Professor of Zoölogy, University of Texas, *511 W. 33rd St., Austin, Texas.*

HEATH, HAROLD, A.B. (Ohio Wesleyan), Ph.D. (Pennsylvania), Professor of Invertebrate Zoölogy, Leland Stanford University, *Palo Alto, Calif.*

HECHT, SELIG, Ph.D. (Harvard), Assistant Professor of Physiology, *Creighton Medical College, Omaha, Neb.*

HEGNER, ROBERT W., B.S., M.S. (Chicago), Ph.D. (Wisconsin), Instructor in Protozoölogy, School of Hygiene and Public Health, *Johns Hopkins University, Baltimore, Md.*

HEILBRUN, L.V., Ph.D. (Chicago), Instructor in Zoölogy, *University of Michigan, Ann Arbor, Mich.*

HENCHMAN, ANNIE P., *Box 34, Jaffrey, N. H.*

HERRICK, CHARLES JUDSON, Ph.D. (Columbia), Professor of Neurology, Anatomical Laboratory, *University of Chicago, Chicago, Ill.*

HERRICK, FRANCIS HOBART, A.B. (Dartmouth), Ph.D. (Johns Hopkins), D.Sc. (Pittsburgh), Professor of Biology, Western Reserve University, *Adelbert College, Cleveland, Ohio.*

HESS, WALTER N., A.B. (Oberlin), A.M., Ph.D. (Cornell), Professor of Biology, De Pauw University, *Greencastle, Indiana.*

HICKERNELL, L. B., A.B., A.M., Ph.D. (Princeton), Assistant Professor of Zoölogy, Syracuse University, *1052 Ackerman Ave., Syracuse, N. Y.*

Hilton, William Atwood, B.S., Ph.D. (Cornell), Professor of Zoölogy, Pomona College, Claremont, California; Director Laguna Marine Biological Laboratory; Editor, Journal of Entomology and Zoölogy, *Claremont, Calif.*

Hogue, Mary Jane, A.B. (Goucher), Ph.D. (Würzburg), Fellow in Protozoölogy, School of Hygiene and Public Health, *Johns Hopkins University, 821 Charles St., Baltimore, Md.*

Holmes, Samuel J., B.S., M.S. (California), Ph.D. (Chicago), Professor of Zoölogy, *University of California, Berkeley, Calif.*

Hooker, Davenport, B.A., M.A., Ph.D. (Yale), Professor of Anatomy, University of Pittsburgh, School of Medicine, *University of Pittsburgh, Pittsburgh, Pa.*

Houser, Gilbert Logan, B.S., M.S. (Iowa), Ph.D. (Johns Hopkins), Professor of Animal Biology and Director of the Laboratories of Animal Biology, State University of Iowa, *430 Iowa Avenue, Iowa City, Iowa.*

Howard, A. D., B.S., (Amherst), M. S. (Northwestern), Ph.D. (Harvard), Scientific Assistant, United States Bureau of Fisheries, Fairport Biological Laboratory, *United States Biological Laboratory, Fairport, Iowa.*

Hunt, Harrison Randall, B.S., Allegheny College, M.A., Ph.D. (Harvard), Professor of Zoölogy, University of Mississippi, *Oxford, Miss.*

Huntsman, Archibald Gowanlock, B.A., (M.B. Toronto), F.R.S.C. (Canada), Professor of Marine Biology, Biological Department, *University of Toronto, Toronto, Canada.*

Hussakof, Louis, B.S. (College of the City of New York), Ph.D. (Columbia), Curator of Ichthyology, American Museum of Natural History, *1537 50th Street, Borough Park, Brooklyn, N. Y.*

Huxley, Julian Sorell, B.A. (Oxford), Senior Demonstrator, Department of Zoölogy and Comparative Anatomy, Fellow of New College, Oxford, *The Museum, Oxford, England.*

Hyde, Roscoe Raymond, A.B., A.M. (Indiana), Ph.D. (Columbia), Associate in Immunology, School of Hygiene and Public Health, *Johns Hopkins University, 310-312 W. Monument St., Baltimore, Maryland.*

Hyman, L. H., Ph.D. (Chicago), Research Assistant, University of Chicago, *Hull Zoölogical Laboratory, University of Chicago, Chicago, Illinois.*

Ibsen, Heman Lawritz, B.S., M.S., Ph.D. (Wisconsin), Professor of Genetics, Department of Animal Husbandry, *Kansas State Agricultural College, Manhattan, Kan.*

Isely, Frederick B., B.S. (Fairmount), M.S. (Chicago), Professor of Biology, *Culver-Stockton College, Canton, Mo.*

Jacobs, Merkel Henry, A.B., Ph.D. (Pennsylvania), Assistant Professor of Zoölogy, Zoölogical Laboratory, *University of Pennsylvania, Philadelphia, Pa.*

Jennings, Herbert S., B.S. (Michigan), A.M., Ph.D. (Harvard), LL.D. (Clark), S.D. (Michigan), Henry Walters Professor of Zoölogy and Director of the Zoölogical Laboratory, *Johns Hopkins University, Baltimore, Md.*

Jewell, Minna E., A.B. (Colorado College), A.M., Ph.D. (Illinois), Assistant Professor of Zoölogy, *Milwaukee-Downer College, Milwaukee, Wisconsin.*

Job, Thesle T., A.B., A.M., Ph.D., Associate Professor of Anatomy, Loyola University School of Medicine, *706 S. Lincoln St., Chicago, Ill.*

Johannsen, Oskar Augustus, B.S. (Illinois), A.M. (Cornell), Ph.D. (Cornell), Professor of Entomology, Cornell University, College of Agriculture, *234 Parkway, Ithaca, N. Y.*

JOHNSON, CHARLES EUGENE, B.A., M.A., Ph.D. (Minnesota) Assistant Professor of Zoölogy, University of Kansas, *616 West 17th Street, Lawrence, Kansas.*

JOHNSTON, JOHN B., Ph.D. (Michigan), Professor of Comparative Neurology, University of Minnesota, *Minneapolis, Minn.*

JORDAN, HARVEY ERNEST, B.A., M.A. (Lehigh), Ph.D. (Princeton), Professor of Histology and Embryology, *University of Virginia, Charlottesville, Va.*

JUDAY, CHANCEY, A.B., A.M. (Indiana), Biologist, Wisconsin Geological and Natural History Survey; Lecturer in Zoölogy, *University of Wisconsin, Madison, Wisconsin.*

JUST, ERNEST EVERETT, Ph.D. (Chicago), Professor of Zoölogy, *Howard University, Washington, D. C., 412 T Street, Washington, D. C.*

KAMPMEIER, OTTO F., B.A. (Iowa), Ph.D. (Princeton), Professor and Director of the Department of Anatomy, Marquette School of Medicine, *4th and Reservoir Sts., Milwaukee, Wis.*

KEPNER, WILLIAM ALLISON, A.B., A.M. (Franklin and Marshall College, Lancaster, Pa.), Ph.D. (Virginia), Associate Professor of Biology, University of Virginia, *University, Va.*

KINCAID, TREVOR, B.S., M.A. (University of Washington), Head of Department of Zoölogy, *University of Washington, Seattle, Wash.*

KINDRED, JAMES ERNEST, A.B., A.M., Ph.D. (Illinois), Instructor in Biology, *Western Reserve Dental School, Cleveland, Ohio, 1353 E. 9th St., Cleveland, Ohio.*

KING, HELEN DEAN, A.B. (Vassar), A.M., Ph.D. (Bryn Mawr), Assistant Professor of Embryology, The Wistar Institute of Anatomy and Biology, *The Wistar Institute, Thirty-sixth St. and Woodland Ave., West Philadelphia, Pa.*

KINGSBURY, BENJAMIN FREEMAN, Ph.D. (Cornell), M.D. (Freiburg), Professor of Histology and Embryology, Cornell University, *2 S. Avenue, Ithaca, N. Y.*

KINGSLEY, JOHN STERLING, A.B. (Williams), Sc.D. (Princeton), Professor of Zoölogy, *University of Illinois, Urbana, Ill.*

KIRKHAM, WILLIAM BARRI, B.A., M.A., Ph.D. (Yale), Assistant Professor of Biology, Sheffield Scientific School, Yale University, *103 Everit Street, New Haven, Conn.*

KNOWER, HENRY McE., A.B., Ph.D. (Johns Hopkins), Professor of Anatomy, Medical Department, *University of Cincinnati, Cincinnati, Ohio.*

KOFOID, CHARLES ATWOOD, A.B., Sc.D. (Hon.) (Oberlin), A.M., Ph. D. (Harvard), Sc.D. (Hon.) (University of Wales). Professor of Zoölogy and Assistant Director of the Scripps Institution for Biological Research, *University of California, Berkeley, Calif.*

KORNHAUSER, SIDNEY, A.B. (Pittsburgh), A.M. Ph.D. (Harvard), Professor of Zoölogy, *Denison University, Granville, O.*

KRECKER, FREDERIC H., A.B., Ph.D. (Princeton), A.M. (Cornell), Assistant Professor of Zoölogy, *Ohio State University, Columbus, Ohio.*

KRIBS, HERBERT GUY, A.B. (Oberlin), Ph.D. (Pennsylvania), B.A. (Union), Assistant in Zoölogy, *University of Pennsylvania, Philadelphia, Pa.*

KUDO, ROKUSABURO, D.Ag.Sc. (Tokio), Instructor in Zoölogy, *University of Illinois, Urbana, Illinois.*

KUNKEL, BEVERLY WAUGH, Ph.B., Ph.D. (Yale), Professor of Biology, *Lafayette College, Easton, Pa.*

KUNTZ, ALBERT, B.A. (Morningside), Ph.D. (State University of Iowa), M.D. (St. Louis University School of Medicine), Professor of Anatomy and Biology, *St. Louis University School of Medicine, 1402 S. Grand Ave., St. Louis, Mo.*

LANDACRE, FRANCIS LEROY, A.B. (Ohio), Ph.D. (Chicago), Professor of Anatomy, *Ohio State University, Columbus, Ohio.*

LANE, HENRY HIGGINS, Ph.B. (DePauw), A.M. (Indiana), Ph.D. (Princeton), Professor of Zoölogy, *Phillips University, East Enid, Oklahoma.*

LA RUE, GEORGE R., B.S. (Doane), A.M. (Nebraska), Ph.D. (Illinois), Assistant Professor of Zoölogy, *University of Michigan, Ann Arbor, Mich.*

LASHLEY, KARL SPENCER, A.B. (West Virginia), M.S. (Pittsburgh), Ph.D. (Johns Hopkins), Assistant Professor of Psychology, *University of Minnesota, Minneapolis, Minn.*

LAURENS, HENRY, A.M. (Charleston), Ph.D. (Harvard), Assistant Professor of Biology, Yale College, Osborn Zoölogical Laboratory, *Yale University, New Haven, Conn.*

LEE, THOMAS G., B.S., M.D. (Pennsylvania), Professor of Comparative Anatomy, *University of Minnesota, Institute of Anatomy, Minneapolis, Minn.*

LEFEVRE, GEORGE, A.B., Ph.D. (Johns Hopkins), Professor of Zoölogy, *University of Missouri, Columbia, Mo.*

LILLIE, FRANK R., B.A. (Toronto), Ph.D. (Chicago), Professor of Embryology and Chairman of the Department of Zoölogy, University of Chicago; Director, Marine Biological Laboratory, Woods Hole, Mass., *University of Chicago, Chicago, Ill.*

LILLIE, RALPH S., A.B. (Toronto), Ph.D. (Chicago), Biologist, Nela Research Laboratories, Department of Pure Science, *Nela Research Laboratories, Nela Park, Cleveland, Ohio.*

LINTON, EDWIN, A.B., S.M. (Washington and Jefferson), Ph.D. (Yale), 1408 Rosemary Lane, Columbia, Mo.

LIPPINCOTT, WILLIAM ADAMS, A.B. (Illinois College), S.B. (Iowa State), S.M. Ph.D., (Wisconsin), Professor of Poultry Husbandry and Poultry Husbandman, Kansas State Agricultural College, *Manhattan, Kansas.*

LOCY, WILLIAM ALBERT, Ph.D. (Chicago), Sc.D. (Hon.) (Michigan), Professor of Zoölogy and Director of the Zoölogical Laboratory, Northwestern University, *1745 Arrington Ave., Evanston, Ill.*

LONG, JOSEPH A., S.B., A.M., Ph.D. (Harvard), Assistant Professor of Embryology, University of California, *1534 La Loma Avenue, Berkeley, Cal.*

LONGLEY, WILLIAM, M.A., Ph.D. (Yale), Professor of Biology, *Goucher College, Baltimore, Md.*

LUND, ELMER J., Ph.D. (Johns Hopkins University), Assistant Professor of Zoölogy, *University of Minnesota, Minneapolis, Minn.*

LUTZ, FRANK E., A.B. (Haverford), A.M., Ph.D. (Chicago), Associate Curator of Invertebrate Zoology, American Museum of Natural History, *77th Street and Central Park West, New York City.*

LYNCH, RUTH STOCKING (Mrs.), A.B. (Goucher), Ph.D. (Johns Hopkins), Independent Research, *The Johns Hopkins Medical School, 3A Seville Apartments, Lake Drive, Baltimore, Md.*

MCCLUNG, C. E., Ph.G., A.B., A.M., Ph.D. (Kansas), Professor of Zoölogy, University of Pennsylvania, Chairman Division of Biology and Agriculture, *National Research Council, Washington, D. C., or Zoölogical Laboratory, University of Pennsylvania, Philadelphia, Pa.*

McCLURE, CHARLES F. W., A.B., A.M. (Princeton), D.Sc. (Columbia), Professor of Zoölogy, *Princeton University, Princeton, N. J.*

McCULLOCH, IRENE, Ph.D. (California), Professor of Biology, Sophie Newcomb College, *New Orleans, La.*

MACCURDY, HANSFORTH M., A.B. (Ohio Wesleyan), A.M., Ph.D. (Harvard), Professor of Biology, Alma College, *701 Center St., Alma, Mich.*

MACDOWELL, EDWIN CARLETON, A.B. (Swarthmore), S.M., Sc.D. (Harvard), Research Investigator, Station for Experimental Evolution, Carnegie Institution of Washington, *Cold Spring Harbor, Long Island, N. Y.*

MACGILLIVRAY, ALEXANDER DYER, Ph.D. (Cornell), Associate Professor Systematic Entomology, University of Illinois, *603 West Michigan Ave., Urbana, Ill.*

McGREGOR, JAMES HOWARD, B.S. (Ohio State University), M.A., Ph.D. (Columbia), Associate Professor of Zoölogy, *Columbia University, New York City.*

McINDOO, NORMAN EUGENE, A.B., A.M. (Indiana), Ph.D. (Pennsylvania), Insect Physiologist, *Bureau of Entomology, Washington, D. C.*

MAGATH, THOMAS BYRD, Ph.B. (Emory University), M.S. (Millikin University), Ph.D. (University of Illinois), M.D. (University of Illinois), Parasitologist, *Mayo Clinic, Rochester, Minn.*

MARK, EDWARD L., A.B. (Michigan), Ph.D. (Leipzig), LL.D. (Michigan), LL.D. (Wisconsin), Hersey Professor of Anatomy and Director of the Zoölogical Laboratory, Harvard University, *109 Irving Street, Cambridge, Mass.*

MARSHALL, RUTH, B.S., M.S. (Wisconsin), Ph.D. (Nebraska), Professor of Biology, *Rockford College, Rockford, Ill.*

MARSHALL, WILLIAM STANLEY, B.S. (Swarthmore), Ph.D. (Leipzig), Associate Professor of Entomology, University of Wisconsin, *139 East Gilman Street, Madison, Wisconsin.*

MAST, SAMUEL OTTMAR, B.S. (Michigan), Ph.D. (Harvard), M.Pd. (Michigan Normal College), Professor of Zoölogy, *Johns Hopkins University, Baltimore, Md.*

MAVOR, JAMES WATT, B.A. (Cantab.), Ph.D. (Harvard), Assistant Professor of Zoölogy, *Union College, Schenectady, N. Y.*

MAY, HENRY G., S.B. (Rochester), Ph.D. (Illinois), Professor of Bacteriology Rhode Island State College and Chief, Division of Animal Breeding and Pathology, Agr. Exp. Station, *Kingston, R. I.*

MEAD, ALBERT DAVIS, A.B. (Middlebury), A.M. (Brown), Ph.D. (Chicago), Sc.D. (Pittsburgh), Professor of Biology, Brown University, *283 Wayland Avenue, Providence, R. I.*

METZ, CHARLES W., B.A. (Pomona), Ph.D. (Columbia), Station for Experimental Evolution, Carnegie Institution of Washington, *Cold Spring Harbor, Long Island, N. Y.*

MEYER, ARTHUR WILLIAM, B.S. (Wisconsin), M.D. (Johns Hopkins), Professor of Anatomy, Stanford Jr. University, *121 Waverly Street, Palo Alto, Cal.*

MIDDLETON, AUSTIN RALPH, A.B., Ph.D. (Johns Hopkins), Professor of Zoölogy, Director of Department of Biology, *University of Louisville, 1st and Chestnut Sts., Louisville, Ky.*

MINNICH, DWIGHT ELMER, A.B. (Miami), Ph.D. (Harvard), Instructor in Animal Biology, *University of Minnesota, Minneapolis.*

Moenkhaus, William J., A.B. (Indiana), Ph.D. (Chicago), Professor of Physiology, Indiana University, *501 Fess Avenue, Bloomington, Ind.*

Moody, Julia Eleanor, B.S., M.A. (Mt. Holyoke), Ph.D. (Columbia), Associate Professor of Zoölogy, Wellesley College, *15 Appleby Road, Wellesley, Mass.*

Moore, Carl R., B.S., A.M. (Drury), Ph.D. (Chicago), Instructor in Zoölogy, *University of Chicago, Chicago, Ill.*

Morgan, Ann Haven, A.B., Ph.D. (Cornell), Professor of Zoölogy, *Mt. Holyoke College, South Hadley, Mass.*

Morgan, Thomas Hunt, B.S. (Kentucky), Ph.D. (Johns Hopkins), Professor of Experimental Zoölogy, *Columbia University, New York City.*

Morgulis, Sergius, A.M. (Columbia), Ph.D. (Harvard), Professor of Biochemistry and Physiology, *Creighton University Medical School, Omaha, Neb.*

Morrill, Albro David, B.S., M.S. (Dartmouth), Professor of Biology, *Hamilton College, Clinton, Oneida County, N. Y.*

Morrill, Charles V., A.M., Ph.D. (Columbia), Assistant Professor of Anatomy, Cornell University Medical College, *28th Street and First Avenue, New York City.*

Mosher, Edna, B.S. (Cornell), Ph.D. (Illinois), Acting Professor of Biology, *University of New Mexico, Albuquerque, N. Mex.*

Mullenix, Rollin Clarke, A.B., A.M. (Wheaton), Ph.D. (Harvard), Professor of Zoölogy, Lawrence College, *461 Washington St., Appleton, Wisconsin.*

Muller, Herman J., A.B., A.M., Ph.D. (Columbia), Dept. of Zoölogy, Univ. of Texas, Austin, Texas.

Muttkowski, Richard Anthony, A.B., A.M., Ph.D. (Wisconsin), Assistant Professor of Zoölogy and Entomology, University of Idaho, *Moscow, Idaho.*

Nabours, Robert K., Ph.D. (Chicago), Professor of Zoölogy and Experiment Station Zoölogist, *Kansas Agricultural College, Manhattan, Kansas.*

Nachtrieb, Henry Francis, B.S (Minnesota), Professor of Animal Biology and Head of the Department, *University of Minnesota, Minneapolis, Minn.*

Neal, Herbert Vincent, A.B., A.M., Ph.D. (Harvard), Professor of Zoölogy, Tufts College, *57 Midford Hillside, Tufts College, Mass.*

Nelson, James Allen, Ph.B. (Kenyon College), Ph.D. (Pennsylvania), Collaborator Bureau of Entomology, U. S. Department of Agriculture, *Route 3, Mount Vernon, Ohio.*

Nelson, Thurlow, Chase B.A. (Rutgers), Ph.D. (Wisconsin), Asst. Professor of Zoölogy, Rutgers College, Biologist, State Board of Shell Fisheries, *855 Adelaide Ave., New Brunswick, N. J.*

Newman, Horatio Hackett, B.A., (McMaster), Ph.D. (Chicago), Professor of Zoölogy and Dean in the College of Science, *University of Chicago, Chicago, Ill.*

Norris, Harry Waldo, A.B., A.M. (Grinnell), Professor of Zoölogy, *Grinnell College, Grinnell, Iowa.*

Nowlin, Nadine (Miss), A.B., A.M. (Kansas), Assistant Professor of Zoölogy, *University of Kansas, 1144 Louisiana St., Lawrence, Kansas.*

Nutting, C. C., A.B., A.M. (Blackburn University), Professor of Zoölogy, *State University of Iowa, Iowa City, Iowa.*

O'Donoghue, Charles H., D.Sc. (London), F.Z.S., Professor of Zoölogy, *University of Manitoba, Winnipeg, Canada.*

Olmsted, J. M. D., Ph.D. (Harvard), Instructor in Physiology, Toronto University, *Toronto, Canada.*

Osborn, Henry Fairfield, A.B., Sc.D. (Princeton), LL.D. (Hon.) (Trinity, Princeton, Columbia), D.Sc. (Hon.) (Cambridge University), Ph.D. (Hon.) (University of Christiana, Upsala); Research Professor of Zoology, Columbia; President Board of Trustees, American Museum Natural History; Curator Emeritus, Department of Vertebrate Paleontology, Vertebrate Paleontologist, United States Geological Survey; American Museum of Natural History, *Seventy-seventh Street and Central Park West, New York City.*

Osborn, Henry Leslie, A.B. (Wesleyan), Ph.D. (Johns Hopkins), Professor of Biology, Hamline University, *1500 Hewitt Avenue, St. Paul, Minn.*

Osborn, Herbert, B.Sc., M.Sc., D.Sc. (Iowa State College), Research Professor Ohio State University, *1952 Concord Road, Upper Arlington, Columbus, Ohio.*

Osburn, Raymond C., Ph.D. (Columbia), Professor of Zoölogy, *Ohio State University, Columbus, Ohio.*

Packard, Charles, M.S., Ph.D., *Peking Union Medical College, Peking, China.*

Painter, Theophilus Shickel, A.B., (Roanoke) A.M., Ph.D. (Yale), Adjunct Professor of Zoölogy, *University of Texas, Austin, Texas.*

Parker, George Howard, S.B., Sc.D. (Harvard), Professor of Zoölogy, Harvard University, *16 Berkeley Street, Cambridge, Mass.*

Parshley, H. M., A.B., A.M., Sc.D. (Harvard), Associate Professor of Zoölogy, Smith College, *Department of Zoology, Smith College, Northampton, Mass.*

Patten, Bradley Merrill, A.B. (Dartmouth), A.M., Ph.D., (Harvard), Assistant Professor of Histology and Embryology, Western Reserve University Medical School, *1353 East 9th Street, Cleveland, Ohio.*

Patten, William, B.S., (Harvard) M.A., Ph.D. (Leipzig), Professor of Zoölogy, *Dartmouth College, Hanover, N. H.*

Patterson, John Thomas, B.S. (Wooster), Ph.D. (Chicago), Professor of Zoölogy, University of Texas, *University Station, Austin, Texas.*

Payne, Fernandus, A.B., A.M. (Indiana), Ph.D. (Columbia), Professor of Zoölogy, Indiana University, *Bloomington, Indiana.*

Pearl, Raymond, A.B. (Dartmouth), Ph.D. (Michigan), D.S. (Dartmouth), LL.D. (Maine), Professor of Biometry and Vital Statistics, School of Hygiene and Public Health, *Johns Hopkins University, Baltimore, Md.*

Pearse, Arthur Sperry, B.S., A.M. (Nebraska), Ph.D. (Harvard), Professor of Zoölogy, *University of Wisconsin, Madison, Wis.*

Peebles, Florence, A.B. (Goucher), Ph.D. (Bryn Mawr), Associate Professor of Physiology, Bryn Mawr College, *Bryn Mawr, Pa.*

Perkins, Henry F., A.B. (Vermont), Ph.D. (Johns Hopkins), Professor of Zoology, University of Vermont, *205 South Prospect Street, Burlington, Vt.*

Petrunkevitch, Alexander, Ph.D. (Freiburg), Assistant Professor of Zoology, *Sheffield Scientific School Zoölogical Laboratory, Yale University, New Haven, Conn.*

Phillips, Everett Franklin, A.B. (Allegheny), Ph.D. (Pennsylvania), Agriculturalist, Bureau of Entomology, *United States Department of Agriculture, Washington, D. C.*

Piersol, George Arthur, M.S. (Pennsylvania), Sc.D. (Pennsylvania College), Professor of Anatomy, University of Pennsylvania, *4724 Chester Avenue, Philadelphia, Pa.*

PIKE, FRANK H., A. B., (Indiana) Ph.D. (Chicago), Associate Professor of Physiology, Columbia University, *437 West 59th Street, New York City.*

POWERS, EDWIN B., Instructor in Zoölogy, *University of Nebraska, Lincoln, Neb.*

PRATT, HENRY SHERRING, A.B. (Michigan), A.M., Ph.D. (Leipzig), Professor of Biology, *Haverford College, Haverford, Pa.*

RAND, HERBERT WILBUR, A.B. (Allegheny, Harvard), A.M., Ph.D. (Harvard), Associate Professor of Zoölogy, Harvard University, *Museum of Comparative Zoölogy, Cambridge, Mass.*

RANSOM, BRAYTON HOWARD, B.Sc., M.A., Ph.D. (Nebraska), Chief Zoölogical Division, Bureau Animal Industry, United States Department of Agriculture, *Bureau of Animal Industry, Washington, D. C.*

REED, HUGH DANIEL, B.S., Ph.D. (Cornell), Professor of Zoölogy, Cornell, *McGraw Hall, Ithaca, N. Y.*

REESE, ALBERT MOORE, A.B., Ph.D. (Johns Hopkins), Professor of Zoölogy, *West Virginia University, Morgantown, W. Va.*

REIGHARD, JACOB ELLSWORTH, Ph.B. (Michigan), Professor of Zoölogy, Director of Zoölogical Laboratory and Biological Station, *University of Michigan, Ann Arbor, Michigan.*

REINKE, EDWIN EUSTACE, M.A. (Lehigh), Ph.D. (Princeton), Assistant Professor of Biology, *Vanderbilt University, Nashville, Tenn.*

RICE, EDWARD LORANUS, A.B. (Wesleyan), Ph.D. (Munich), Professor of Zoölogy, *Ohio Wesleyan University, Delaware, Ohio.*

RICHARDS, A., B.A. (Kansas), M.A. (Wisconsin), Ph.D. (Princeton), Professor of Zoölogy, Dept. of Zoölogy, Univ. of Oklahoma, Norman, Okla.

RICHARDS, MILDRED H., A.B. (Goucher), A.M., Ph.D. (Columbia), Dept. of Zoölogy, Univ. of Oklahoma, Norman, Okla.

RIDDLE, OSCAR, A.B. (Indiana), Ph.D. (Chicago), Resident Investigator Carnegie Institution of Washington, *Cold Spring Harbor, Long Island, N. Y.*

RILEY, WILLIAM ALBERT, B.S. (Depauw), Ph.D. (Cornell), Professor of Entomology, University of Minnesota, *University Farm, St. Paul, Minnesota.*

RITTER, WILLIAM E., B.S. (California), Ph.D. (Harvard), Director of Scripps Institution of Biological Research of the University of California, Professor of Zoölogy, University of California, *La Jolla, Calif.*

ROBERTS, ELMER, B.S., Ph.D. (University of Illinois), Associate in Genetics, University of Illinois, *College of Agriculture, Urbana, Ill.*

ROBERTSON, ALBERT DUNCAN, B.A. (Toronto), Professor and Head of Department of Biology, Western University, *Dept. of Biology, Western University, London, Ont., Canada.*

ROBERTSON, ALICE, B.S., M.S., Ph.D. (California), Assistant Professor of Zoölogy, *Wellesley College, Wellesley, Mass.*

ROBERTSON, W. REES BREBNER, A.B. (Kansas), Ph.D. (Harvard), Associate Professor of Zoölogy, University of Kansas, *1701 Louisiana Street, Lawrence, Kansas.*

ROGERS, CHARLES GARDNER, A.B., A.M. (Syracuse), Ph.D. (California), Professor of Comparative Physiology, Oberlin College, *378 Reamer Place, Oberlin, Ohio.*

ROGERS, FRED TERRY, A.B., Ph.D. (Chicago), Professor of Physiology, Baylor Medical College, Dallas, Texas

ROOT, FRANCIS METCALF, A.B., A.M. (Oberlin), Ph.D. (Johns Hopkins), Teaching Fellow in Medical Entomology, *School of Hygiene and Public Health, Johns Hopkins University, 310–312 West Monument St., Baltimore, Md.*

RUTHVEN, ALEXANDER G., B.S. (Morningside), Ph.D. (Michigan), Director Museum of Zoölogy, Professor of Zoology, University of Michigan, *Museum of Zoölogy, Ann Arbor, Mich.*

SCHAEFFER, ASA ARTHUR, A.B. (Franklin and Marshall), Ph.D. (Johns Hopkins), Professor of Zoölogy, *University of Tennessee, Knoxville, Tenn.*

SCHIEDT, RICHARD C. F., Ph.D. (Pennsylvania), Sc.D. (Hon.) (Franklin and Marshall), *Lancaster, Pa.*

SCOTT, JOHN W., A.B., A.M. (Missouri), Ph.D. (Chicago), Professor of Zoölogy, Research Parasitologist, *University of Wyoming, Laramie, Wyoming.*

SCOTT, GEORGE G., A.B., A.M. (Williams), Ph.D. (Columbia), Chairman Department of Biology, *College of the City of New York, New York City.*

SCOTT, WILL, Ph.D. (Indiana), Associate Professor of Zoölogy, *Indiana University, Bloomington, Indiana.*

SHELFORD, VICTOR ERNEST, B.S., Ph.D. (Chicago), Associate Professor of Zoölogy, University of Illinois, and Biologist in charge of Research Laboratories, Natural History Survey, *The Vivarium, Wright and Healy Sts., Champaign, Illinois.*

SHOREY, MARIAN LYDIA, A.M., Ph.B. (Brown), Ph.D. (Chicago), *Huguenot College, Wellington, South Africa.*

SHULL, AARON FRANKLIN, A.B. (Michigan), Ph.D. (Columbia), Associate Professor of Zoölogy, University of Michigan, *520 Linden Street, Ann Arbor, Mich.*

SIGERFOOS, CHARLES P., B.S. (Ohio State), Ph.D. (Johns Hopkins), Professor of Zoölogy, *University of Minnesota, Minneapolis, Minn.*

SMALLWOOD, WILLIAM MARTIN, Ph.D. (Harvard), Professor of Comparative Anatomy, Syracuse University, *525 Euclid Avenue, Syracuse, N. Y.*

SMITH, BERTRAM GARNER, A.B. (Michigan), Ph.D. (Columbia), Associate Professor of Zoölogy, Michigan State Normal College, *122 College Place, Ypsilanti, Mich.*

SMITH, ELIZABETH ANITA, A.B. (Cincinnati), M.A., Ph.D. (Wisconsin), Assistant Professor, *University of Wisconsin, Biology Bldg., Madison, Wisconsin.*

SMITH, FRANK, Ph.B. (Hillsdale College), A.M. (Harvard), Professor of Systematic Zoölogy, *University of Illinois, Urbana, Ill.*

THE ANATOMICAL RECORD, VOL. 20, NO. 3,
FEBRUARY, 1921

Resumen por el autor, Juan C. Nañages,
Universidad de Filipinas.

Dos casos de corazón monoventricular con atresia y transposición de algunas de las raices de los grandes vasos.

En 118 corazones de niños filipinos, estudiados por el autor con referencia al orificio oval (foramen ovale) se hallaron dos corazones monoventriculares. La presente contribución presenta una descripción morfológica de estos dos casos de corazón monoventricular, encontrados en dos varones, uno de ellos de dos horas, el otro de cuatro dias de edad. En el primer caso se comprobó la existencia de un ventrículo derecho sumamente pequeño, con el tabique interventricular desplazado y el orificio atrio- ventricular derecho ocluido. En el segundo caso se notó la existencia de un tabique interventricular incompleto, acompañado de ausencia completa del orificio mitral. El autor discute ambos corazones con relación a su probable desarrollo y fisiología. Los casos de corazón monoventricular son compatibles con el desarrollo intraruterino normal, pero cuando están asociados con estenosis pulmonar, aún en el caso de existir un conducto arterial patente, la vida puede mantenerse tan solo durante unas pocas horas después del nacimiento.

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED
BY THE BIBLIOGRAPHIC SERVICE, DECEMBER

TWO CASES OF MONOVENTRICULAR HEART WITH ATRESIA AND TRANSPOSITION OF SOME OF THE ROOTS OF THE GREAT VESSELS

JUAN C. NAÑAGAS

Department of Anatomy, University of the Philippines

EIGHT FIGURES (TWO PLATES)

In the course of a series of examinations that the writer undertook on a collection of Filipino infant hearts, for the special study of the foramen ovale, he encountered among 118 two instances of peculiar abnormalities that were thought of sufficient interest not only from the embryological viewpoint, but also from their physiological importance in relation to the viability of the fetus, as to warrant this brief descriptive report.

Congenital malformations of the heart do not usually interest many readers of medical literature, for the reason that they are often classed as "mere developmental curiosities of the human organism" devoid of special clinical significance to the general practitioner. Though this may be true to a certain extent in the two cases that I am now reporting, nevertheless, it must be borne in mind that some of these instances of defective cardiac development are quite compatible with life, and are of sufficiently common occurrence as to render their recognition not only important, but even essential to clinical medical men. Cases have been recorded where individuals have lived for years with cardiac malformations. In life, these patients must have undoubtedly exhibited definite but undiagnosed clinical pictures, which could have been recognized and a more rational treatment prescribed had their clinical consideration been carried in conjunction with corresponding anatomical and physiological studies. Gladstone, in his paper on cardiac malformations, emphasizes particularly this point when among other things he stated:

It is of greatest importance that the signs and symptoms produced by these different types of cardiac malformation should be carefully studied in all cases and recorded, so that an opportunity will be afforded of comparing one case with another, and of diagnosing the kind of abnormalities during life. In order to complete our knowledge of these cases, however, it remains for clinicians to correlate the signs and symptoms which these different malformations of the heart produce. It will then be possible to recognize the type of malformation during the patient's lifetime, and to carry out the treatment of individual patients upon a rational basis.

It is intended to present in this paper, first, the anatomical conditions of the abnormalities found in each case, and then to offer a tentative explanation of their possible embryological origin and the probable cardiac circulations occurring during intra and extra-uterine life.

ANATOMICAL FINDINGS

Case 1. The first specimen was the heart of a male Filipino infant that lived only two hours after birth. The case came to the city morgue from one of the health districts of the city, and for this reason no clinical history could be obtained except that the baby lived for about two hours. In opening the heart by routinary incisions I was surprised to observe that there were only three cardiac chambers, viz., the right and left auricles and a considerably enlarged ventricle. External examination showed that what should have been considered at a glance as the trunk of the pulmonary artery, with its prominent anterior position and left upward course, was really the ascending root of the aorta with its wide communication to the single ventricle. The real pulmonary artery was found only after a careful search, as a small poorly developed vessel on the left anterior side of the aortic trunk closely adherent to it, and apparently, from the outside at least, continuous with the base of the ventricle (fig. 1, *B* and *C*). The great cardiac vein together with the anterior coronary artery, that normally course downward to the apical notch of the heart, were considerably shifted to the right of the median line running obliquely to the right border of the ventricle (fig. 1, *A*).

This heart weighed 17.2 grams, or 0.81 per cent of the body weight, the latter being 2,114 grams. Its greatest circumference taken at the base of the ventricle was 96 mm. and its longest diameters were 46 mm. vertically, 37 mm. transversely, and 21 mm. anteroposteriorly. The ratio of the weight of the heart to the body weight in this case is a trifle greater than the normal ratio as given by Jackson (0.77 per cent) and Vierordt (0.76 per cent) in newly born infants. The difference of 0.04 to 0.05 per cent is in reality sufficiently small to warrant the conclusion that this heart, at least in weight, has attained its normal state of development.

On careful internal examination of the single ventricle no trace could be seen of the existence of any separation of this chamber into right and left halves. The right lateral wall, however, showed a marked thickening of the cardiac musculature, which extended medially, as far as a line coinciding externally, with the oblique course of the anterior coronary artery described above (figs. 2 and 3). An anteroposterior cut through the thickness of this part of the wall showed the muscle fibers in close relation anteriorly and superiorly with the rudimentary trunk of the pulmonary artery, from which point they appeared to stream obliquely downward and posteriorly. The excessive thickness of this part has produced a corresponding internal swelling into the cavity of the ventricle at its right lateral side. This fact would seem to indicate that this internal swelling probably represented the rudiment of an interventricular septum which might have become arrested in its development.

The single ventricle in this heart therefore is in reality the left ventricle which had become compensatingly enlarged. In the cavity of the ventricle there were found two large and several small papillary muscles and many trabeculae carnae (figs. 2 and 3). The principal papillary muscles were normal in location for the left ventricle, one of them arising from the left anterior wall and the other from the posterior wall. The cordae tendinae from these papillary muscles extended to the medial angles of the anterior and posterior cusps of the mitral valve and were attached to their margins.

The circumference of the left auriculoventricular orifice in this case was 35.5 mm. From cardiac measurements of ninety-six still-born infants made by me I had obtained a normal average of 24.5 mm. for the circumference of this opening. It seems, therefore, that the excess of 11 mm. would be accounted for by the fact that this orifice's being the only communication between the auricles and the ventricle it had probably become compensatingly enlarged.

The other communication that the single ventricle had was with the aorta. The circumference of this aortic orifice measured 16.5 mm., a little more than my normal average figure, which was 14 mm. This opening was guarded by three semilunar cusps, two anterior, slightly shifted to the left in the direction of the pulmonary artery, and one posterior. Each of these cusps showed well-developed sinuses, from two of which the right and left coronary arteries originated as in normal cases. The vessel leading from the ventricle through this orifice, though from its external position would correspond to the pulmonary artery, is nevertheless undoubtedly the aorta because of the facts above considered, viz., the position of the guarding semilunar valves and the origin of the coronary arteries and because of the greater thickness of its wall.

The right auriculoventricular orifice examined from the auricular side is oval in shape with its long axis directed transversely and its circumference measuring approximately 17 mm. Its margins are sharply defined and the flaps of the valve were completely fused together forming a 7-mm. pit underneath the orifice. Several small openings were found at the bottom of this pit which on a sagittal section showed them to open into blind crevices lodged in the right thickened part of the ventricular wall (figs. 2 and 3, *C*). This fact seems to further confirm the statement that the medial portion of this thickened wall represented a rudimentary interventricular septum. The crevices into which the openings of the flaps led were probably the remains of an imperfectly developed right ventricle, which conclusion is still more justified by the organic connection of the fibers of the ventricular wall in this neighborhood and the roof of the obliterated

pulmonary artery as previously recorded. The bundles of fibers found between these crevices were possibly diminutive papillary muscles.

The imperfectly developed trunk of the pulmonary artery was only about one-fifth the size of that of the aorta and was partly hidden from view by the left auricular appendix. On opening the artery proximally it was found to terminate blindly in three small sinuses which did not appear to have any connection with either the ventricle or the crevices found beneath the occluded right auriculoventricular orifice. Two of these sinuses were posterior and slightly medial in position, while the other was anterior. They were limited by three embryonic semilunar valves fused together and exhibiting thickened borders at the lines of fusion. Below this level the ventricular wall appeared on section to be entirely solid; the infundibulum or conus arteriosus was therefore entirely arrested in its formation. From the right posterior wall of the pulmonary artery about 2 cm. from its root arose the patent ductus arteriosus, which was about as large as the pulmonary trunk itself and established a free communication with the ascending aorta (fig. 1).

The foramen ovale was patent, the aperture between the free edges of the independent septum primum and septum secundum measured 4 sq. mm. The septum primum, however, was greatly relaxed, bulging considerably into the left atrium. This condition was possibly due to the irremediable free flow of blood from the right to the left sides of the heart.

Case 2. This heart was that of a poorly nourished full-term male Filipino baby that lived only four days postpartum. It showed harelip and polydactilism of both hands. Its body weight was 1,640 grams, sitting height 30 cm. and standing height 46 cm.

It will be noticed that the body weight in this case was far below the average given for normal newly born European and American babies as given by various investigators (over 3,000 grams) and a little below the average obtained by me for apparently normal Filipino still-born babies (2,200 grams).

Its standing height was only a trifle below the average figures given for American and European still-born babies, which was about 49 cm.

The differences of these two measurements from the normal averages would seem to indicate that while the development of the body was about normal, it was undoubtedly ill nourished.

From the shape of the heart alone one would readily anticipate the presence of some abnormalities. The vertical diameter was markedly in excess to the width. It weighed 17.7 grams, or 1.07 per cent of the body weight. This ratio was higher than in our first case and considerably greater than the figures given by Jackson and Vierordt. The greatest circumference of this heart was 92 mm., the largest vertical diameter was 47 mm., the transverse 36 mm., and the anteroposterior 26 mm.

The anterior surface represented by the anterior half of the right atrium and the ventricle was massive and much larger than the posterior surface. It was divided into a larger triangular right anterior facies and a narrower roughly quadrangular surface at the left by a linear elevation of the ventricular wall running from the base above to the apex of the ventricle below. The wall of the ventricle at the upper end of this right anterior portion was elevated in a marked upward prominence considerably deepening the auriculoventricular sulcus at this point (fig. 4).

The conus arteriosus was entirely absent and the pulmonary artery could not be seen on the normal point of its origin from the ventricles. The only vessel seen originating directly from the latter was the aorta, which appeared much larger than normal, and its ascending portion showed a funnel-shaped enlargement as it approached the arch. In position this vessel was shifted considerably to the left, arising from the upper third of the left ventricular border at a point considerably below the auriculoventricular sulcus. Unlike the ordinary condition, the aorta in this case followed an upward course, inclining immediately to the left so that its ascending portion was directly on the left upper ventricular wall, and only the arch came into relation with the left side of the atrium. The tip of the auricular appendix was barely touching the arch at its beginning.

On opening the right atrium by an incision following its greatest superior curvature, it was found to consist of an apparently dilated cavity into which three openings were found, two at its posterior wall corresponding to the superior and inferior venae cavae, and one found inferiorly leading into the ventricle, the auriculoventricular orifice.

On examining the posterior wall of this atrium from the outside, four smaller vessels, presumably the four pulmonary veins, were seen, which, however, did not directly open into the large cavity described above, but into a small flattened space adjoining the posterior atrial wall, which undoubtedly represented a rudimentary left atrium. This cleft-like space was separated from the enlarged right auricle by an interatrial septum in which an oval opening guarded by a thin septum was seen. This opening which was the foramen ovale appeared normal in every respect.

No communication between the left auricle and the ventricle was found. The only communication, therefore, between the ventricle and the atrial portion of this heart was represented by the right auriculoventricular orifice, which measured approximately 42 mm. in circumference.

Internally the ventricular portion of this heart showed only a single vertically elongated cavity, in which no recognizable division between a right and a left portion could be found. There was, however, a more or less prominent ridge situated in the middle of the posterior wall of the cavity, which by its position could be considered as representing the septum interventriculare (figs. 5 and 6). If such were the case, then this heart would have undivided right and left ventricles in their embryological condition, closely resembling in this manner the amphibian type of heart. The right portion of this ventricular cavity was in direct communication with the single enlarged atrium. The left side was continued upward and posteriorly to form the root of the aorta, while anterosuperiorly it gradually merged with a small elongated blind space found inside the peculiarly bulging portion of the anterior surface of the base of the ventricle (fig. 4).

The ventricular wall as a whole was massive, averaging about 6 mm. in thickness. Two small papillary muscles were present,

one situated in front and the other posteriorly, with their cordae tendinae attached to the edges of the flaps of the single auriculoventricular orifice. This opening possessed but two flaps, differing in this respect from the normal, which has three.

The aortic opening, as in normal hearts, was guarded by three semilunar cusps, two found anteriorly and one posteriorly. The three aortic sinuses (sinuses of Valsalva), were found to be dipping down into the wall of the ventricle to a much greater extent than in normal cases. The ascending aorta, as noted above, was funnel-shaped and joined the aortic arch upward posteriorly. The latter was likewise fairly dilated.

Only the right coronary artery originated from the right aortic sinus. It coursed downward in a zigzag direction for a short distance in the posterior coronary sulcus, which it soon left to run along the posterior or diaphragmatic surface of the heart, curving toward the left border considerably above the apex, and anastomosing at this point in a plexiform manner with the anterior descending branch of the left vessel. The left coronary arose directly from the anterior wall of the ascending aorta. On reaching the level of the root of this vessel in its descent, it followed forward and to the right, the anterior coronary sulcus under cover of the right auricle until it reached its extreme right end; thence the artery coursed along the right ventricular margin as far as the apex, where it resolved into plexiform anastomoses.

Another striking anomaly found in connection with the aorta was the presence of two fairly good-sized branches originating from its posterior wall about half a centimeter from its proximal end. These vessels were found to correspond with the right and left pulmonary arteries, the common pulmonary trunk being absent. This peculiar condition was not noticed until after the removal of the heart, and the identification of these two vessels was based upon a careful search and topographic comparison of their cut cardiac and pulmonary ends. The diameters of these two vessels were approximately 4 mm. for the right and 3 mm. for the left.

REVIEW OF LITERATURE

In reviewing the literature at our command for cases showing similar cardiac malformations, we found the following:

1. Three-chambered hearts. Keith ('09), in his extensive review of 272 cases, established three types of three-chambered hearts, viz., *a*) hearts in which the interventricular septum was so little developed, or in which the interventricular foramen was so large that the two ventricles were rightly said to form one chamber; *b*) those cases where the right ventricle was suppressed by the septum's being applied to the right side of the heart, and, *c*) those in which the left ventricle was suppressed by the interventricular septum closely shifted to the left ventricle wall of the ventricle.

He found in his set nine cases belonging to the first type with associated arterial transpositions; seven cases to the second type, five of which showed complete obliteration of the right ventricle and two with the two ventricles forming a common chamber, and in every case the infundibulum was well developed. Of the third type he found five cases. In the second and third groups the absence of a ventricle was associated with a complete or almost complete obliteration of the corresponding auriculo-ventricular orifice.

Young ('07) and Dixon Mann ('07) reported a case of an adult man aged 35 years whose heart showed complete absence of the septum interventriculare with associated transposition of the arterial trunks. Paterson ('08–'09) reported a similar cardiac malformation in a man 22 years old. Both cases belong properly to the second type.

Gladstone ('15–'16) cited two cases of this cardiac anomaly, one from a child 48 hours old where the left ventricle was rudimentary and functionless and which therefore would fall under group 3, and the other case, a woman 50 years of age with a heart showing a patent foramen interventriculare with constriction of the ostium bulbi; which could be included under type 1.

Dickson and Frazer ('13) had a case in a male child 3 months old. The specimen showed a hypertrophy of both ventricles

with incomplete development of the interventricular septum. This instance could be included in the first type. It was asso ciated with an abnormal origin of the pulmonary artery.

Keith ('12) mentioned four other cases where the interventricular foramen showed varying degrees of patency found in individuals from 9 months to 16 years of age, associated with such anomalies as closure of the auriculoventricular orifice, undeveloped ventricle, and closure of the pulmonary orifice, etc. Three of these cases properly belonged to the first type, but one case, with undeveloped condition of the right ventricle, could also be considered as belonging to type 2. He also cited a case of a child 48 hours old where the heart showed obliteration of the left ventricle and the corresponding auriculoventricular orifice. This case of course belonged to type 3.

Black ('13–14) reported two cases: one heart, belonging to an adult male 22 years of age, showed a large interventricular foramen with associated malformations of the pulmonary cusps; the other was that of a male child 6 months old with a patent foramen interventriculare and a marked reduction of the size of the aorta with no associated anomaly of the infundibulum. These two might rightly be included under type 1.

Our first case belongs to type 2, as it shows a diminutive right ventricle with the interventricular septum shifted to the right side. The second case that had an incomplete septum is to be included in type 1 of Keith's classification. In case 1 there was a complete obliteration of the right auriculoventricular orifice from fusion of the flaps. Case 2 showed a complete absence of the mitral opening.

2. Arrest in the developmental expansion of the infundibulum. Keith ('09) encountered thirty-seven cases of such condition. The typical picture of such cases had the infundibulum reduced to a mere slit situated at the orifice of the pulmonary artery which was generally represented by a small cicatricial mass, or a very small lumen in which the fused semilunar valves could be distinguished. The pulmonary artery was in the majority of cases represented by a fibrous cord at its origin.

In the case of Dickson and Fraser ('13) the right pulmonary artery originated from a point ½ inch above the commencement of the ascending aorta and the left from the descending portion.

Keith ('12) mentioned a case in a male child 11 months old where the infundibulum was obliterated and the pulmonary artery received blood from the ductus arteriosus.

Peterson's ('08–'09) case showed besides, a marked stenosis of the pulmonary orifice with a substitution of the pulmonary valves by a thick pad of cardiac tissue.

In our cases, the first showed the pulmonary arterial trunk markedly reduced in size and the pulmonary orifice entirely closed from fusion of the semilunar flaps. In the second case the pulmonary trunk was entirely absent, and the two small arterial vessels identified as the pulmonary arteries were seen arising from the posterior side of the aorta.

3. Atrophy of the auricular portion of the heart. Keith ('09) met three cases which showed considerable diminution in the size of the left auricle associated with complete stenosis of the mitral orifice. He stated that such cases might easily have escaped detection and could have been considered as two-chambered hearts—a rare condition which, even with his wide experience on the subject, he had never yet seen.

Our second case shows undeveloped left atrium together with absence of the left auriculoventricular orifice.

4. Incomplete separation of the aorta and pulmonary artery. Irregularities in the division of the truncus arteriosus, which becomes divided to form the root of the aorta and the pulmonary artery, according to Keith, are rare. He had only seen three cases in his series. Rakitansky reported a case with this condition, but with the pulmonary artery considerably larger than that found in our case.

Our second case showed incomplete separation of the pulmonary artery from the ascending aorta and two small vessels representing the pulmonary arteries arising directly from the posterior side of the beginning of the aortic root, which in turn was considerably shifted to the left side of the heart.

EMBRYOLOGICAL CONSIDERATIONS

Owing to the various possibilities which could be considered in our cases, it would seem rather difficult to definitely offer any explanation that would adequately cover the different embryological factors which might have led to the production of the anomalies herein enumerated.

1. Monoventricular condition. In our first case we encountered a suppression of the right ventricle by the septum's being applied to the right side of the heart. In the second case the two ventricles were imperfectly separated by defects in the interventricular septum.

We have failed to find in our search of the literature any author who endeavored to explain the first condition.

It is a well-known fact that at some stage of the normal development of the heart there is a time when the so-called ventricular limb starts its division into a greater left and a smaller right half, to be later known as the left and right ventricles, respectively, by the production on its external convex surface of a groove and within its cavity of an interventricular septum.

If at this period of development by some unknown reason the normal proportionate development of parts were arrested or at least changed to an unequal growth, similar anomalies would probably result. Thus if we were to suppose at this stage a delayed or even an arrested growth of the right side of the heart, with consequent continued and relatively increased development of the left, a condition would result where the left cardiac cavity would appear greatly enlarged, with the septum apparently reduced to a mere parietal thickening shifted well to the right, and the right ventricular cavity represented by mere crevices or by a diminutive cavity hardly large enough to permit the unfolding of the tricuspid valves. This condition is exactly similar to that encountered in our first specimen.

Our second case of monoventricular heart with imperfect separation of the two ventricles by defect in the interventricular septum has been encountered and explained by several writers on this subject. Gladstone explains the persistence of the inter-

ventricular foramen as an apparently secondary condition to the failure in the expansion of the bulbar portion of the right ventricle, and says that its presence and size depend largely upon the extent of the defect. Hunter and Keith hold the same view, i.e., that the interventricular foramen is produced by the obstruction or stenosis of the pulmonary artery and that the closure of the interventricular foramen depends on the complete development of the infundibulum. Keith further states that from 85 to 90 per cent of the cases with pulmonary stenosis showed an interventricular foramen.

Meckel, as cited by Keith ('09), claimed, on the other hand, that the interventricular foramen is a primary condition and the pulmonary stenosis its sequence.

Young asserts that the course of the main blood-stream inside of the heart could interfere with the complete development of the interventricular septum.

The monoventricular condition in our second case may be explained perhaps by an arrest of growth of the interventricular septum, which in this case is represented by a mere ridge in the ventricular floor. This septal condition is similar to its early stage of development in the division of the embryonic ventricle into two halves. This arrest is undoubtedly due to the mechanical pressure and friction exerted upon it by the flow of blood coming through the right auriculoventricular orifice and which not finding any exit at the right ventricular side because of the total absence of a pulmonary artery is forced toward the left side of the ventricle to find there its only orifice of escape represented by the aorta (fig. 8).

The abnormal and excessive upward prominence of the ventricular wall in its anterosuperior base must also be looked upon as a necessary result of the same continued increased pressure exerted upon that part of the ventricle by the blood-stream passing through the aortic orifice. This influence is certainly conceivable, if we remember that the arterial pulmonary trunk should have taken origin from this region, and that the tender embryonic cardiac musculature is very apt to give way to such a persistent and continued mechanical factor.

2. Congenital stenosis of the pulmonary orifice with or without arrest of the developmental expansion of the infundibulum. Keith explains the majority of those cases of congenital pulmonary stenosis associated with arrested development of the infundibulum as due to a failure of the bulbus cordis to incorporate with the right ventricle. In those cases where the stenosis is not, however, associated with an arrested infundibulum, he believes foetal endocarditis to be responsible for the defect.

In this connection we quote from Gladstone the following:

> According to Schipman, the most common and important effect of intra-uterine endocarditis is stenosis of the pulmonary orifice, and he also states that the limitation of the endocarditis to the right side of the organ during intra-uterine life comes under the same law as its limitation to the left side in extra-uterine life. In both cases it is the cavity which has most work to perform that is affected. According to this view, cases in which the interventricular foramen has not persisted are produced by endocarditis occurring after the period when this foramen is normally closed. The closure is effected by the fusion of the interventricular septum with the bulbar septum, and this takes place in embryos between 12 mm. and 18 mm. in length, and at the age of six or seven weeks. It is possible, however, that the endocarditis is a secondary incident which has occurred after birth, and that the primary condition is constriction. It is probable also that the constriction is attributable to a primary defect in development rather than to a foetal endocarditis; for if foetal endocarditis were the cause, we should expect also to find stenosis of the right auriculo-ventricular orifice with endocarditis of the tricuspid valve, but this is not found, on the contrary congenital stenosis of the right auriculo-ventricular orifice is extremely rare.

In our two cases we found a complete absence of the infundibulum, associated in the first case with a diminutive pulmonary artery and stenosis of the pulmonary orifice by fusion of its similunar valves and with complete absence of the pulmonary artery and pulmonary orifice in the second.

These defects plus the absence of any inflammatory signs in the perfectly smooth and shiny fused pulmonary flaps incline us to believe that neither foetal endocarditis nor the failure of incorporation of the bulb into the right ventricle would furnish satisfactory explanations.

In normal cases we know that the separation of the bulb into the aortic and pulmonary trunks is the result of the fusion of the right and left distal bulbar swellings and the septum aortopulmonale. These swellings are linear thickenings of the endocardial surface of the bulb, two at its proximal and four at the distal portion. The union of the right and left distal bulbar swellings is generally produced by the ingrowth of the connective tissue of the bulbar wall. This fusion together with the approaching septum aortopulmonale brings about the complete division of the bulbar trunk into a ventral vessel, the aorta and a dorsal pulmonary artery. The two proximal swellings by their spiral direction complete further this division by bringing each vessel into a more direct relation with its corresponding ventricle. The semilunar valves of the aortic trunk are formed by the anterior distal bulbar swelling and the two anterior halves of the right and left laterally. Those of the pulmonary artery by the posterior and the posterior halves of the right and left distal lateral swellings.

Now it is possible that in the first case, owing to inequality in growth of the ventricle, the union of the right and left bulbar swellings with the septum aortopulmonale has taken place, but considerably shifted to the anterior side of the bulb. This shifting has necessarily reduced the pulmonary artery to a diminutive trunk, and its semilunar valves, remaining diminutive and crowded together, have become completely fused.

In the second case the septum aortopulmonale has probably failed to descend and meet the bulbar swellings, leaving in this manner the truncus arteriosus undivided, and the pulmonary arteries arising directly from the ascending aorta. Such condition would also account for the absence of the pulmonary orifice.

3. Rudimentary and collapsed condition of the left auricle. As regards the rudimentary and collapsed state of the left atrium and the absence of its atrioventricular orifice, it does not seem possible to offer as reasonable explanations as in the anomalies already considered above, we might, however, conceive such abnormality as due to a probable combination of such two factors as:

a. A possible arrest or entire failure of development of the two endocardial cushions which should normally appear in the ventral and dorsal walls of the heart in the region of the atrioventricular sulcus, together with fusion of this sulcus with the interatrial septum in the side of the left atrium.

b. Normally developed cushions which after their union were shifted to the left to meet and fuse with the atrioventricular sulcus in this side. This condition, if combined with an arrest of further development of the left atrium with a compensatory enlargement of the right side, would give rise to a condition similar to that found in our specimen.

Such a combination of factors influencing the production of the above abnormalities could only be made possible by the total absence or diminished amount of blood flowing into the left atrium as a result of the absence of the arterial pulmonary trunk.

The four pulmonary veins probably transmitted little blood if any at all into the left atrium, two vessels which were taken as representing the pulmonary arteries being altogether too small to carry on any appreciable pulmonary circulation.

PHYSIOLOGICAL CONSIDERATIONS

Probable cardiac circulation in the two cases. A morphological study of the circulation, both during the intra-uterine and postpartum lives, in both cases would indeed be of some interest.

Case 1. Prenatal circulation in this case is obviously possible and could normally be carried on to full term without greatly impairing the normal general development of the foetus.

The arterialized blood from the placenta undoubtedly followed a normal circuit by passing successively through the right and left atria (freely communicating with each other by a patent and relaxed foramen ovale), to the single ventricle through the widely open mitral orifice, and thence to the general circulation, passing out of the aortic root.

A satisfactory explanation of the postpartum circulation in this case would offer several difficulties. Literatures on cardiac malformations mention only a few instances where three-cham-

bered hearts were found in adult individuals. Cases with complete atresia of the pulmonary orifice, as in the case under consideration, have never been known to live for more than twenty-four hours. In such instances where a complete arrest of the infundibulum was present, the lungs, according to Professor Keith, were supplied with blood from the systemic circulation through the bronchial arteries and other accessory branches of the intercostals. It is unfortunate that we were unable to obtain a complete clinical history of our case; this would probably have helped us in our explanation by knowing the behavior of the child after delivery.

It is of course possible to conceive that the pulmonary circulation could be carried in one of the two following ways:

a. The lungs may receive some blood via the bronchial arteries and intercostal branches, as explained by Professor Keith. We regret that we were unable to study the bronchial arteries of this specimen. We question, however, the ability of such circulation to sustain life for any length of time in our case because of the almost complete absence of any expanded lung tissue in either side. The child lived only two hours.

b. Pulmonary circulation might be possible also by the blood passing successively from the right auricle to the left atrium through the foramen ovale, thence to the left ventricle through the mitral orifice, therefrom into the aorta from which a small amount of blood could enter the ductus arteriosus in the reverse direction and eventually reach the lungs via the pulmonary artery (figs. A and B).

The great downward obliquity of the ductus arteriosus in its union with the aorta, its relatively small size, and the reverse direction of the collateral stream incline us to believe that only a small amount of blood, if any at all, could possibly reach the lungs by this route. If we add further to the above facts, the venous condition of the blood thus circulating, we almost wonder how the child could have lived even for two hours as it did, unless the oxygenation of its blood from the placenta could have carried him through that length of time.

Case 2. The foetal circulation in utero in this case undoubtedly followed a similar route as in case 1.

The postpartum circulation offers to a certain extent similar difficulties as those encountered in case 1.

The pulmonary circulation was carried on again either by the collateral bronchopulmonary circuit of Professor Keith or through the two diminutive pulmonary arteries branching off from the aorta. In either case, however, the return circulation took place through the four diminutive pulmonary veins into the collapsed left atrium and thence through the foramen ovale into the right auricle, completing in this manner the pulmonary circuit.

We believe, however, that the amount of blood reaching the lungs by any one of the above two routes, though probably was greater in amount than in the first case, yet it was without doubt insufficient to support life for any long period. We base this opinion on the great reduction of size of the pulmonary arteries and veins (less than one-third the normal dimensions) and the diminutive collapsed condition of the left atrium, both

of which spell a proportionately reduced blood stream in the entire circuit, which though sufficient to enable the foetus to live for a few days, is nevertheless undoubtedly incompatible with prolonged life. This case lived about four days.

CONCLUSIONS

In closing, we would like to draw attention to the following points of interest:

1. The incidence of monoventricular hearts among the Filipino babies is apparently not a very rare condition. In our series we encountered them in the proportion of 1.6 per cent. This fact would seem to call for a more careful clinical study of newly born babies showing obscure cardiac symptoms with fatal results.

2. That the ratio of the weight of the heart to the body weight in our cases was considerably greater than the normal ratio as given by Jackson and Vierordt, denoting undoubtedly a compensatory effort on the part of the heart to carry on circulation under abnormal conditions.

3. That not all cases of persistent interventricular foramen can be explained by the failure of expansion of the bulbar portion of the right ventricle or by pulmonary stenosis produced by foetal endocarditis. In many instances it is necessary to invoke also defects of growth, mechanical effect of abnormal blood stream, etc.

4. That the congenital atresia and stenosis of the pulmonary orifice in our cases was probably due to either irregularity of growth of the ventricle and shifting to one side of the union of the right and left bulbar swellings and the septum aorto-pulmonale or to the entire failure of the septum aortopulmonale to unite with the distal lateral bulbar swellings.

5. That monoventricular hearts are perfectly compatible with normal development in intra-uterine life, but when associated with pulmonary stenosis, even with patency of the ductus arteriosus, it is probable that life cannot continue for more than a few days, although the collateral pulmonary circulation might be taken up by branches of the bronchial and intercostal arteries.

I wish to acknowledge my indebtedness to Dr. H. W. Wade, of the Department of Pathology, for allowing me to report case 2, which came to them at the autopsy table, and to Dr. Arturo Garcia for some helpful suggestions in the preparation of this paper.

Resumen por el autor, Harvey Ernest Jordan,
Universidad Washington, Saint Louis.

Nuevas pruebas sobre la función de los osteoclastos.

El autor presenta pruebas histológicas sobre la función histolítica de las células gigantes multinucleadas de la médula ósea mandibular del gato recién nacido. Estas células gigantes contienen glóbulos voluminosos de material óseo reabsorbido, y son osteoclastos genuinos. La pulpa del órgano productor del esmalte contiene también células gigantes semejantes, provistas de glóbulos similares. Estos últimos glóbulos son considerados por el autor como esmalte superfluo reabsorbido y las células gigantes como ameloblastos.

BY THE BIBLIOGRAPHIC SERVICE, DECEMBER 27

FURTHER EVIDENCE CONCERNING THE FUNCTION OF OSTEOCLASTS

H. E. JORDAN

Department of Histology and Embryology, University of Virginia Medical School

FIVE FIGURES

In a recent paper on the giant cells of the yolk-sac and the bone marrow, the writer (4) included a brief description of 'osteolytic giant-cells' ('osteoclasts' of Koelliker) in the mandibular marrow of the new-born cat. In this paper a distinction was made between the 'hemogenic' and the 'osteolytic' giant-cells of the bone-marrow. The hemogenic giant-cells were shown to develop by excessive growth from hemoblasts. By amitotic division of their transiently polymorphous nucleus these cells become multinucleated, and in this condition occasionally differentiate intracellular erythrocytes. The osteolytic giant-cells 'originate by the aggregation of many nuclei in certain areas which then become separated to form large irregular syncytia, which may fuse with or incorporate osteoblasts and bone cells. These syncytia become placed upon spicules of bone, which they resorb' (p. 241) (4). The hemogenic giant-cells are accordingly comparable to multiple erythroblasts or blood islands; the osteolytic giant-cells are comparable to foreign-body giant-cells. In the osteoclasts were described globules of a substance with the identical structure and staining reaction of the adjacent spicules of bone. These globules were interpreted as resorbed osseous material. This observation constitutes the sole recorded direct evidence that the so-called osteoclasts actually ingest bony substance. The only other approximately direct evidence that these giant-cells possess an osteolytic function is that recorded by Koelliker (5). Following Tomes and de Morgan (7) and Billroth (2) he drove ivory pegs into bone. Subsequent study

of this experimentally modified material showed an extensive pitting of these pegs, with multinucleated giant-cells occupying an occasional pit. Tomes and de Morgan, and Billroth, however, regarded these pits in the ivory pegs as eroded through the agency of connective tissue.

Arey (*1*) questions the adequacy of the evidence above outlined as signifying a specific osteolytic function on the part of the so-called osteoclasts. He concludes, moreover, that the hypothesis 'that they are merely degenerating, fused osteoblasts, accords better with the known facts' (p. 335). It seemed desirable, therefore, to devote a renewed and more extensive study to my preparations in which the giant-cells showed these 'osseous globules.' The chief purpose of this investigation is to enlarge the body of evidence touching the function of these giant-cells as judged by their cytology and to subject the same to a more rigidly critical analysis. Questions concerning the origin and fate of the osteoclasts will not be here further considered. It is necessary to draw a sharp distinction in this connection between an osteolytic or osteoclastic function and a mere phagocytosis of already fragmented and decalcified bone of resorption foci. The evidence seems unequivocal as concerns an osseophagic function of these cells. The central point at issue concerns the active and efficient agent in the dissolution and decalcification of the disappearing spicules of bone in bone development and growth. It should be stated here that Koelliker (*6*), in his second extensive paper on bone resorption, no longer regards his experimental evidence with ivory pegs as conclusively indicating a specific osteolytic function of the osteoclasts. He inclines to ascribe some osteolytic function in growing bones also to the medullary and periosteal connective tissue.

The material upon which this investigation is based consists of sections of the lower jaw of a new-born cat. The tissue was fixed with Zenker's fluid, decalcified in a 5 per cent aqueous nitric-acid solution, imbedded in celloidin, cut at 12μ, and stained with hematoxylin and eosin. We are interested here in both the alveolar bone and the included teeth; that is, in the multinucleated giant-cells with osseous globules both of the bone-marrow and of the enamel pulp.

The character of the material is shown in figure 1. The bone is of the cancellous membranous type, with remnants of 'cartilage bone' formed in Meckel's cartilage of the fetal mandible. The tooth is of course of the deciduous series, and of a stage of development several months prior to eruption. The tooth is

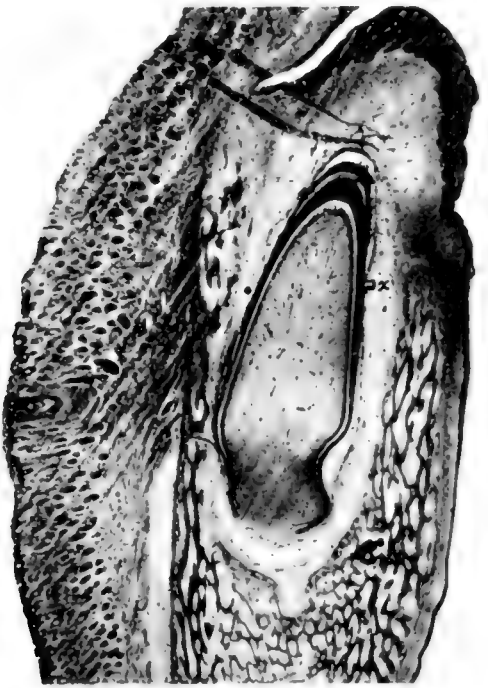

Fig. 1 Photomicrograph of transverse section of lower jaw of new-born cat, including tooth. × 12. Over the crown of the tooth the remnant of the enamel pulp has shrunken away from the enamel. Photos by Mr. William S. Dunn, Cornell University Medical College, New York City.

enveloped apically by the primordium of the future cuticular membrane (of Nasmyth) consisting of remnants of the ameloblasts, the enamel pulp (with its inner stratum intermedium), and the peripheral enamel epithelium. The enamel pulp contains numerous multinucleated giant-cells, some with globules of a material apparently identical with that of the osteoclasts, others in process of degeneration and disintegration.

We may to best advantage consider the osteoclasts first. As already stated, these contain larger and smaller globules of a substance with apparently the identical homogeneous structure and acidophilic staining reaction as the spicules of membrane bone (figs. 3 to 5). These ingested globules are commonly located in the portion of the giant-cell next the bone; but occasionally they may apparently lie in the portion farthest removed from the bone (figs. 4 and 5). The latter condition in certain cases is to be interpreted in terms of an adjacent spicule of bone in a higher or lower plane. In figure 4 is shown a giant-cell in process of ingesting a large pestle-shaped mass of free bone. These illustrations would seem to admit of no doubt concerning the osseophagic capacity of these giant-cells. The globular, sharply contoured form of the phagocytosed osseous material indicates that it is ingested only in a fluid or semisolid condition; that is, after a preparatory decalcification of portions of the bony spicule. In figure 5, at the left, is shown a large, relatively clear, circular area, probably representing an osseous globule in a late stage of digestion.

The suggestion has been made to me that these globules of bone which I interpret as ingested free portions of bone are actually only extensions of bone within the giant-cells from adjacent spicules. Such suggestion has no pertinency to my descriptions of intracellular globules since it can be proved, by raising and lowering the level of focus, that many globules are actually within the giant-cell protoplasm. An interpretation that presented itself very forcibly to me, not hitherto suggested, and one which I have now thoroughly tested, is that these alleged osseous globules are actually only ingested red blood-corpuscles which either remained isolated or became fused into homogeneous masses. It cannot be denied that these giant-cells do phagocytose erythroplastids as well as osteoblasts and bone cells. Also, some of these smaller globules have approximately the size of a spheroidal erythroplastid. But the red blood-corpuscles of these specimens have a different shape and staining reaction, both in the adjacent blood-vessels and after ingestion by giant-cells. They occur either as cup-shaped,

crenated, or circular biconcave discoid bodies; or they may be variously irregular, or even fragmented. Furthermore, they never exhibit the same deep bluish-red staining reaction; the red blood-corpuscles are either brownish yellow, pinkish brown or light pink in color. In a section of human femoral marrow from a case of fatal typhoid fever, treated with a similar technic, many mononucleated cells can be seen engorged with red blood-corpuscles in all stages of disintegration. In no case, however, is the ingested group of corpuscles fused into a homogeneous mass similar to the globules here described in the osteolytic giant-cells. Moreover, I can find no mention of any condition, either in normal or pathologic histology, where erythroplastids are fused into comparable globules. Nor can these globules be regarded as hyaline degeneration products in view of the generally healthy appearance of these giant-cells.

The question arises as to the active agent in the decalcification and the fragmentation (resorption) of the bone, making possible the ingestion by these giant-cells. There are three obvious possibilities: 1) the medullary connective tissue; 2) the blood-vessels; 3) the giant-cells. If the connective tissue were the specific osteolytic agent in this tissue, we would expect to find numerous globules of bone scattered throughout at least that portion adjacent to the bone spicules. But such globules are lacking in the bone-marrow except occasionally in close proximity to the giant-cells. If the blood-vessels were the effective causative agent in osteolysis in this growing bone, we would expect to find the globules to some extent within the vessels or at least in close proximity to them. Such conditions also do not obtain. Moreover, the vascular supply seems too meager, and is is not generally sufficiently close to the spicule of bone, to furnish plausible support to this assumption. By process of elimination of obviously possible osteolytic agents there remains the osteoclast. This certainly contains globules of ingested osseous material. It is invariably present where bone is being resorbed and reshaped at least during early stages of development. It is generally in close connection at one or several points with the peripheral layer of the bony spicule (figs. 4 and 5).

The evidence from the bone-marrow above described would seem to leave no escape from the conclusion that the giant-cells in this tissue are the active proximate agents in the decalcification and fragmentation, and subsequent ingestion (resorption), of the bone; that is, that they are genuine osteolytic giant-cells or osteoclasts, as originally claimed by Koelliker (5). But this conclusion must be further appraised in the light of data accruing from the study, next to be reported, of the multinucleated giant-cells of the enamel pulp.

I was at first very much surprised to find what appeared to be identical globules both in the general syncytium and in certain multinucleated giant cells of the enamel pulp of the deciduous pre-erupted teeth in these preparations (fig. 2). Globular shape, variable size, sharp contour of borders, homogeneous structure, and similar staining reaction force the conclusion that these globules of the enamel pulp are practically identical with those above described for the giant-cells of the bone-marrow. In the case of the enamel organ, with its 'pulp,' we are dealing with an ectodermal structure invaginated into the primitive jaw from the overlying epithelium. The cells of the basal layer differentiate into ameloblasts which function in the production of the enamel; the intermediate layers form a loose syncytium, and the peripheral layer becomes a thin membrane with cells of endothelioid form. The erupting tooth remains covered with an atrophic membrane, the cuticular membrane of Nasmyth, composed of the nucleated remnants of the ameloblasts, the compressed tooth pulp, and the greatly flattened peripheral enamel epithelium. The erupted crown may remain covered with only ameloblastic remnants.

The possibility presents itself that the 'osseous globules' of the enamel pulp are transported from the marrow, or vice versa. If this were the correct interpretation, such globules should be found in the portion intermediate between the crown of the tooth and the deeper bone-marrow; that is, in the paradental corium of the jaw. The agents in such transference would conceivably have to be either blood-vessels or amelopulpar giant-cells; or possibly the globules might find their way from the

enamel pulp to the alveolar areolae through the operation of gravity. The last suggestion may be dismissed as quite improbable, more especially in view of the fact that no free globules of this sort are found in the intervening connective tissue. If

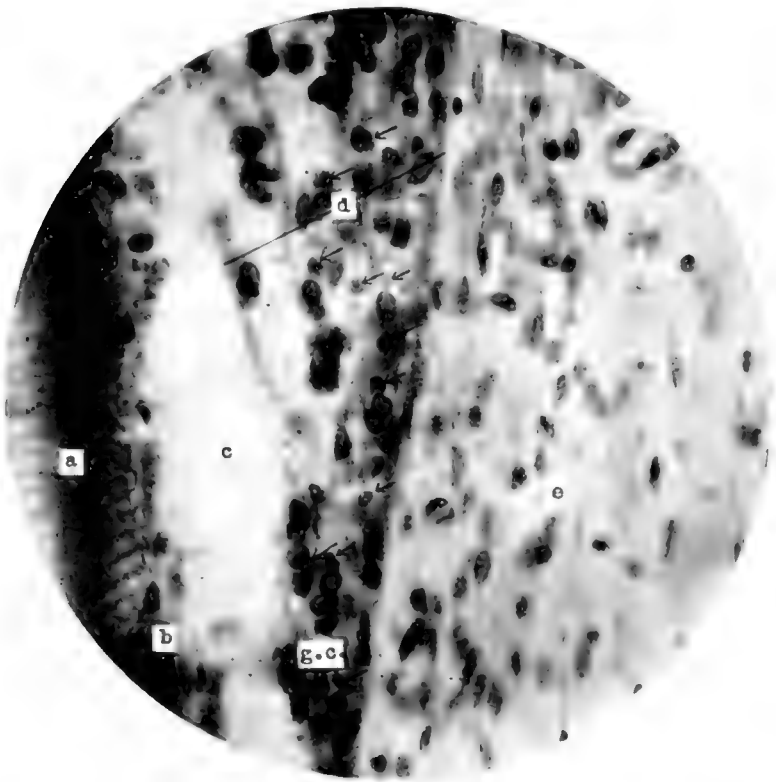

Fig. 2 Photomicrograph of area X of fig. 1. × ca. 600. *a*, enamel; *b*, stratum intermedium of enamel pulp; *c*, fixation (contraction) artifact; *d*, enamel pulp; *e*, connective tissue of the dental sac; *g.c.*, two small multinucleated giant-cells, containing enamel globules. The arrows point to some of the globules within the pulp syncytium. These globules do not differentiate themselves sharply in the photograph from the nuclei of the pulpar cells.

these globules passed either way via the blood-vessels, we would expect to find them also within these vessels; but such globules are entirely absent from the blood-vessels. Moreover, the enamel organ is non-vascular. The terminal blood channels

stop short abruptly upon the outer enamel epithelium of the enamel organ. As regards the giant-cells, none are found just outside the enamel organ in the connective tissue intervening between the lateral border of the tooth and the underlying bone. The possibility of a transportation of these globules from the enamel pulp to the marrow areolae of the alveolar bone or vice versa seems definitely untenable.

We are then confronted with the demand for an explanation of the occurrence of these 'osseous globules' within the enamel pulp and the included giant-cells. These giant-cells are formed in a manner quite similar to that by which the giant-cells of the alveolar bone arise, that is by closer fusion of 'cells' of the pulp syncytium. They form, therefore, in the manner of foreign-body giant-cells. These giant-cells of the enamel pulp certainly ingest the osseous globules; many of which lie free within the pulp, or in vacuoles in the pulp cells, and especially as large free, spheroidal and greatly elongated, globules next the enamel. The giant-cells are phagocytic for these globules, and they subsequently disintegrate by a process initiated by a general karyorrhexis of the multiple nuclei, a stage of which gives a simulacrum of multipolar mitoses. During this process of degeneration the cytoplasm of these cells becomes intensely oxyphilic.

That the globules are not single, or fused masses of, red blood-corpuscles is here even more definitely indicated than in the case of the osteoclasts. Blood-vessels filled with erythroplastids abut upon the enamel organ, so that it is readily possible to bring such a vessel and a portion of the pulp with globules into the same field, when careful comparisons can be made between the two. No blood-vessels can be seen in my preparations entering the enamel organ.[1] The erythroplastids differ in shape, size,

[1] I am unable to confirm the conclusion of Hopewell-Smith that the enamel pulp (stratum intermedium) of the kitten's tooth is supplied with a capillary plexus ("Normal and pathological histology of the mouth," vol. 1, pp. 263-264). His figures 227 and 229, supplied to illustrate his description of a vascularized pulp, do not obviously bear such interpretation. As near as one can determine from these photomicrographs, the capillaries end abruptly on the outer surface of the enamel organ, as in my preparations. Hopewell-Smith introduces this

and staining reaction from the 'osseous globules' in the same manner as above described for the alveolar marrow. It must be added, however, that many of the pulp globules have a sort of brownish-gray, or less deeply bluish-red, color than those of the osteoclasts. This difference may signify a later stage in resorption in the case of the pulp globules. That the globules also in the enamel pulp do not signify hyaline degeneration seems definitely indicated by the generally healthy character of the nuclei of the pulp syncytium.

The crucial point concerns the origin and significance of these pulpar osseous globules. Two possibilities are presented: 1) that they represent decalcified resorbed enamel; 2) that they represent a superfluous enamel secretion on the part of the cells of the enamel pulp, which is then resorbed through the agency of newly formed polynucleated giant-cells. The latter possibility has a color of reasonableness, since the cells of the enamel pulp are originally very similar to those of the adjacent ameloblasts and would accordingly be expected to have similar functional capacities. It is difficult definitely to dispose of this suggestion. There is, however, one datum of at least apparent countervailing significance: large elongated globules occur between the inner border (stratum intermedium) of the enamel organ and the definitive enamel. Moreover, the border of the enamel in such regions appears uneven, and occasionally even jagged, as if enamel were being dissolved peripherally. It would seem probable, in view of this observation, that the newly

subject of the blood-supply of the enamel organ with the statement that "The vascularity or otherwise of the enamel organ is not yet determined, many competent authorities holding opposite opinions on this subject. Thus Lionel Beale, Leon Williams, Howes, and Paulton assert that a vascular network is to be found in the stratum intermedium, while Tomes, Paul, Andrews, Wedl, Sudduth, and Magitot affirm its non-vascularity.

"The author, in a joint paper with H. W. Marett Tims, has recently described the presence of blood-vessels, containing erythrocytes in the enamel organ of the Australian wallaby. ('Tooth germs in the wallaby, Macropus billiardieri'; Proc. Zoolog. Soc., London, 1911)" (pp. 261–262). He then proceeds to describe "The blood supply of the developing dental tissue" in Mammalia and illustrates his description as regards the vascularization of the enamel pulp with a "coronal section through the mandible of a kitten" (pp. 259 and 264), which he interprets as showing pulp capillaries.

formed enamel becomes to some extent resorbed and reshaped peripherally before the deciduous tooth is finally erupted. But in the event that the latter should prove the correct interpretation of the presence of these globules within the enamel pulp, I am quite unable to decide, on the basis of available data, as to whether the active agent of resorption is here the enamel pulp as a whole or specifically the giant-cell (adamantoclast, ameloclast). That the blood-vessels have nothing directly to do with the process of decalcification and resorption of the enamel seems clear from the fact that they are excluded from the enamel organ. But it is to be recognized that blood-vessel intervention in the process of resorption might be viewed as simply the obverse of the logically assumed nutritive rôle of the blood-vessels with respect to enamel elaboration. All things considered, I incline to the view that these globules of the enamel pulp are superfluous secretion products of slightly active potential ameloblasts of the stratum intermedium of the pulp, and that the formation and presence of multinucleated giant-cells signifies the fulfillment of a demand for the removal of the globules by phagocytosis. But the alternative view that the globules are derivatives of the definitive enamel, resorbed either through the agency of the pulp as a whole or specifically through the agency of the newly formed giant-cells is not disproved. Under either view, however, the pulpar giant-cells are ameloclasts in the sense that they ingest and destroy enamel.

The resemblance, or apparent chemical identity, between the globules ingested by the osteoclasts and those of the ameloclasts results from the essential chemical identity between bone and enamel. While the evidence is fairly conclusive that the osteoclasts are the active specific agents in the resorption of bone in these specimens, it warrants for the present only the assertion that the giant-cells of the enamel pulp ingest and destroy enamel globules derived from an unknown source by action of an unknown agency. This source may obviously be either the newly formed enamel or the cells of the pulp syncytium. The obvious active agent in resorption may be either the enamel pulp or the newly formed giant-cells. Less obvious sources and factors cannot, however, at present be definitely excluded.

As regards the osteoclasts, two facts stand in sharp contradiction to Arey's (*1*) conclusion that they should be interpreted as degenerating fused osteoblasts: 1) Osteoclasts arise in large part directly from the connective tissue stroma of the marrow, independently of osteoblasts; 2) the younger osteoclasts exhibit no signs of degenerative changes, either cytoplasmic or nuclear.

SUMMARY

In the mandible of the newborn cat occur many multinucleated giant-cells which contain a variable number of spheroidal globules of a material apparently identical with bone. These giant-cells occur both in the marrow of the developing jaw bone and in the enamel pulp of the developing tooth. Both groups of cells arise in a similar manner; in one case by fusions among the cells of the marrow reticulum, in the other case by fusion of cells of the dental pulp. In respect of the mode of origin, and of their function, these cells accordingly resemble foreign-body giant-cells. The former are osteoclasts, the latter ameloclasts; one group ingests and destroys globules of bone, the other globules of enamel. The fundamental factors operating in the decalcification and dissolution of the bone and of the enamel remain unknown. In the case of the osteoclasts, however, the evidence suggests that the giant-cells are the active specific agents in the dissolution of the bone, as well as in the elimination through phagocytosis of the products of dissolution. The fact that in many other locations where resorption of growing bone occurs, similar giant-cells are very numerous, though without osseous inclusions, is in accord with this view. The presence or absence of the products of resorption in the shape of globules, in the cytoplasm of specific osteolytic giant-cells, may be correlated with the relative rapidity, or perhaps the peculiar mode, of resorption of the bone. The products of osseous resorption of specific osteolytic giant-cells, generally of ultramicroscopic size, may under certain conditions be of microscopic size, like the globules here described for these osteoclasts and ameloclasts.

Resumen por los autores, Paul K. Webb y J. Barrett Brown,
Universidad Washington, Saint Louis.

Un caso de barras costales independientes en e lepistrofeo del hombre.

En el presente trabajo se dá a conocer la existencia de un par de procesos costales independientes en el epistrofeo de un varón negro. Las barras costales consisten en dos osículos independientes de un centímetro y medio de longitud, y del mismo tamaño, que se articulan por medio de una anfiartrosis con protuberancias cortas que se extienden desde el cuerpo del axis. Estas protuberancias ocupan la posición del extremo proximal de la barra costal normal. Las barras costales independientes se extienden inferiormente y lateralmente, sin fundirse con los pedículos posteriores o con los verdaderos procesos transversos. Los orificios costo-transversos son por consiguiente incompletos, abriéndose hacia los lados. En el atlas no existen barras costales; los cuerpos y arcos de la segunda y tercera vértebra son continuos en cierto grado, y esto es probablemente una condición secundaria.

A CASE OF INDEPENDENT COSTAL BARS OF THE EPISTROPHEUS IN MAN

PAUL K. WEBB AND JAMES BARRETT BROWN
Department of Anatomy, Washington University

TWO FIGURES

This rare variation was discovered in the class laboratory during the preparation of the vertebral arteries. The subject was a male negro of advanced age, as indicated by extreme emaciation and wrinkled skin, sparseness of hair, toothless jaws, and fragile bones. The record taken from the mortuary report gave his age at ninety-five years.

On tracing the vertebral arteries through the transverse foramina toward the cranium, our attention was arrested on reaching the epistropheus by the mobility of the two costal bars of that vertebra. Examination disclosed two ossicles, similar in form and of nearly equal size, articulating, one on either side, with the body of the epistropheus (figs. 1 and 2). Each bone presented the shape of a little horn, directed downward, backward, and a little laterally, tapering below to a free blunt extremity. The ossicle is bent into a well-marked curve, convexity forward. That of the right side measured 9 mm. in length and 4 mm. in the greatest diameter; the left bone, 10 mm. and 4 mm. They occupied the usual position of the costal component of the cervical transverse process and were therefore in series with the costal bars of the succeeding vertebrae. The ossicles do not have a true capitular termination against the body of the epistropheus, but articulate with a truncated process springing from the base of the root of the arch just beneath the superior articular surface. A careful preparation of the joint revealed an amphiarthrosis, the articulating surfaces being covered with cartilage, without, however, a joint cavity or synovial layer. The union was maintained by fibrous tissue apparently in con-

nection with the periosteum and tendons of muscles. As already intimated, the joint permitted a small degree of motion of the ossicle. The opposite extremity of the latter ended free, did not articulate, or even come into contact with the truncated process representing the posterior bar of the transverse process. The transverse foramen was therefore open laterally.

Other abnormalities were subsequently discovered more or less closely related to that just described. The lamina and inferior articular process of the left side of the epistropheus are continuous with the lamina and the superior articular process of the third vertebra; bony union also obtains between the third and fourth vertebrae in two regions, viz., between the articular processes of the right side and between the bodies on the left. Some degree of thickening of the articular processes and laminae is noticeable where the union exists. The union between the bodies of the third and fourth is marked by a bony callosity. A certain amount of deformation of the bodies of the fourth and fifth vertebrae, affecting the anterior opposed margins, is evident.

The atlas also presents a variation. This rudimentary bone is still further reduced by the absence of its anterior costal bars. In place of them, there was found on each side a slender ligament completing the transverse foramen anteriorly. This band was stretched between the lateral free extremity (tubercle) of the transverse process of the atlas and a prominent, short, thick process of the lateral mass opposite the front of the superior articular surface. This may be a vestige of the costal bar or a capitular process.

As to the occurrence of like variations, it is of course well known that absence of the costal bar of the atlas has been frequently observed; Macalister ('93), Bolk ('99), and Le Double ('12) in particular have described and discussed the significance of this variation. All degrees of defect of this bar, ranging from nearly its normal size to complete absence, have been noted.

Elliot Smith ('07) has described a case of fusion of the atlas and axis in which there was no evidence of disease. In the present case the cause of fusion between the laminae and articular processes of the epistropheus and third vertebra cannot

with certainty be referred to an inflammatory process; this is probably the cause. The deformation and ankylosis of the bodies are evidently the result of disease; the irregular contour is in contrast with the smoother surface where the axis and third vertebra are continuous by their articular processes. If the latter union were primary, it is not improbable that the fixation of the joints between these bones might have been a predisposing factor in the location of the disease process in the joints of the succeeding vertebrae. The phenomenon of coalescence of vertebrae both as a normal ontogenetic process and as a not uncommon variation is well established by observation: fusion of the cervical vertebrae to constitute a single piece, comparable to the status of the sacrum in man, is normal among cetaceans; there is marked tendency toward fusion of the atlas with the occipital bone in man, as shown by the descriptions of many cases (Dwight, '09; Kollmann, '04; Swjetschnikow, '06, and others). In a large percentage of such cases there is no evidence of disease as an influence in bringing about the fusion.

Regarding the occurrence of independent costal bars in the cervical region, a very large literature has grown up chiefly from interest in cervical ribs. The known cases of cervical ribs have been collected and reviewed by Le Double and additional facts have been brought to light by the more recent work of Todd ('12). The usual type of cervical rib is connected with the seventh vertebra; a rare association is that with the sixth. Szawlowski ('01) has reported a case of costal rudiments in connection with the fourth bone. Macalister ('94) has found an independent bony granule in the pre-arterial crus of the transverse process of the axis. There is evidence, according to Fawcett ('10), of independent chondrification of the costal bars. So far as we know, no cases of vestigial ribs have been found in connection with the atlas, epistropheus, and fifth vertebra. Consideration of all the conditions in the present case lead us to the conclusion that the independent ossicles have developed from centers separate from the ossific processes of the epistropheus and by their relations must be regarded as vestigial ribs. The ossicle represents probably only the neck of a rib, since it

does not reach the true transverse process and at its vertebral end articulates with a prominent process (capitular?) without, however, expanding to form a head. It is comparable to the rib rudiments in the cephalic part of the cervical region of reptiles.

The chief interest of this case, it seems to us, lies in its possible connection with the tendency to regression manifested in so many directions by the components of the head-neck region. Bolk (loc. cit.), who has studied this phenomenon, points out the evidences of this reaction in the reduced state of the atlas and its proneness to further degeneration and assimilation with the occipital; the imperfection of the first spinal nerve correlated with the absence of muscles in the intertransverse and interspinous series, etc. Further consideration of this question has been given by Terry ('17) in connection with the development of the occipital region of the chondrocranium. The present case exhibits a group of changes, differing in kind (defect of atlas, coalescence of vertebrae, abortive development of epistropheus), which may, nevertheless, be the result of a single factor operating upon the formation of this transitional zone between the head and neck.

The authors wish to express their appreciation of the assistance given them by Dr. R. J. Terry in the preparation of this report.

Resumen por F. S. Hammett, por el autor Vincent Vermooten, Universidad del Cabo, Africa del Sur.

Estudio de la fractura del epistrofeo en el ahorcado, con una nota sobre las causas posibles de muerte.

En el presente trabajo el autor presenta una breve descripción anatómica de la naturaleza de las fracturas cervicales observadas en cuatro casos de ejecución judicial en la horca. En todos los casos ha encontrado una dislocación de la segunda y tercera vértebra, en dirección inferior. La primera y segunda vértebra estaban todavía articuladas correctamente, así como el atlas con el occipucio. Puesto que el ligamento transverso conservaba todavía su posición normal, mientras que el arco neural estaba desprendido de la vértebra, el autor cree que este es el resultado ordinario después de morir ahorcado y, por consiguiente, no está conforme con la opinión de Gray, que admite la ruptura del ligamento transverso en tales casos. Vermooten cree que la muerte se debe probablemente a la rotura de la médula.

A STUDY OF THE FRACTURE OF THE EPISTROPHEUS DUE TO HANGING WITH A NOTE ON THE POSSIBLE CAUSES OF DEATH

VINCENT VERMOOTEN

Anatomical Laboratory of the University of Cape Town, South Africa

TWELVE FIGURES

The cause of death due to hanging (judicial hanging), although a very interesting phenomenon, has apparently not been the result of much investigation. It has usually been taken for granted that death is due to rupture of the transverse ligament of the atlas with the resulting crushing of the cord and medulla by the odontoid process of the epistropheus. That this is not always the case is shown by the examination of four cases of hanging which the author investigated in this laboratory during the latter part of the year 1919.

On examination it was found that in all the four cases there was a downward dislocation of the second and third cervical vertebrae. The first and second vertebrae were still properly articulated as well as the atlas with the occiput, the ligamentum apicis dentis being still firmly attached to the occiput and to the tip of the odontoid process of the epistropheus.

Another remarkable fact was revealed: the transverse ligament of the atlas was still in its normal position, holding the odontoid process as in life. There was not even the faintest trace of a rupture of the ligament in any of the four cases.

In the first cases (figs. 1, 2, 3,) the atlas and the epistropheus were well articulated, as were the atlas and occiput. The epistropheus and third cervical vertebra were dislocated downward, while the transverse ligament of the atlas was intact.

The epistropheus, strangely enough, was fractured, the neural arch being altogether broken off from the body. The fracture

on the right side was posterior to the foramen transversarium, but anterior to the inferior articular facet. On the left-hand side the fracture was through the pedicle and through the trans-

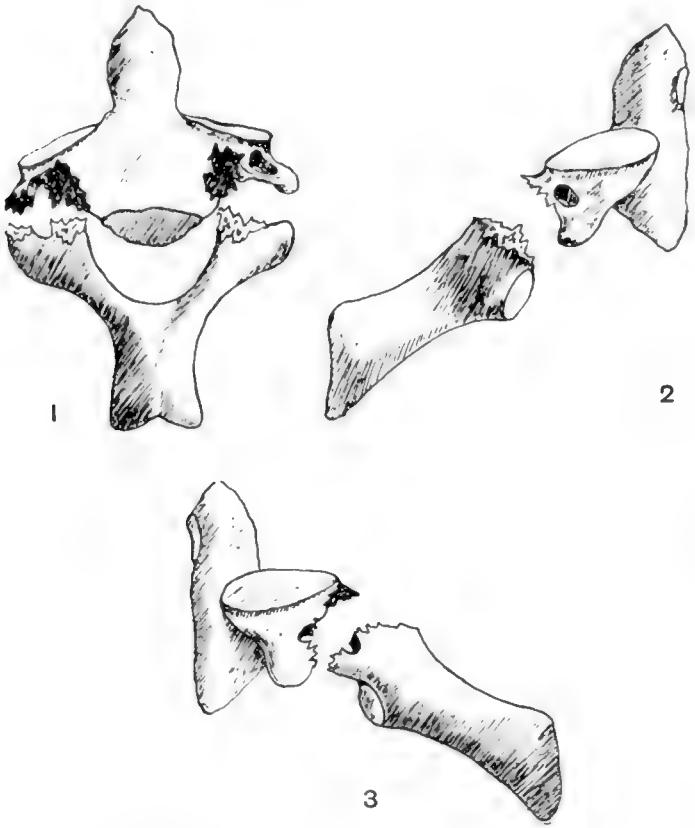

Fig. 1 Body and neural arch of vertebra.
Fig. 2 Portions of vertebra viewed from the right side.
Fig. 3 Portions of vertebra viewed from the left side.

verse element of the transverse process, leaving the greater part of the foramen transversarium anterior to the break.

In the second case (figs. 4, 5, 6) the vertebrae were again articulated as in the first case, with the transverse ligament of

the atlas altogether intact. The neural arch was also fractured on both sides. On the right-hand side the break was anterior to the inferior articular facet and posterior to the foramen transversarium, leaving the foramen quite whole. On the left-hand side there was a break in the same position as on the right, but the sides of the foramen transversarium were also broken so that the transverse process was altogether broken off from the vertebra.

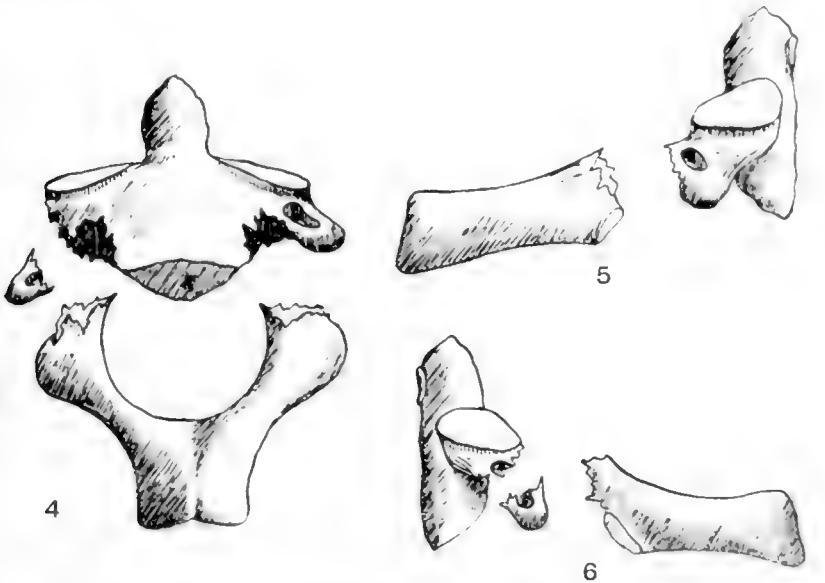

Fig. 4 Body and neural arch of the vertebra.
Fig. 5 Portions of vertebra viewed from the right side.
Fig. 6 Portions of vertebra viewed from the left side.

In the third case (figs. 7, 8, 9) once more the conditions of articulation were as in the previous cases, with absolutely no sign of rupture of the transverse ligament of the atlas and the neural arch was once more totally broken off from the body of the vertebra.

The fracture on the right-hand side was in exactly the same position as the fracture on the right-hand side of the second case. On the left-hand side the fracture was much more serious, for,

in addition to a fracture similar to the one on the right-hand side, there was also a fracture through the pedicle and through the junction of the posterior third and anterior two-thirds of the superior articular facet, anterior to the foramen transversarium. A large part of the arch containing the foramen transversarium was thus broken from the lamina on the one hand and from the body of the vertebra on the other.

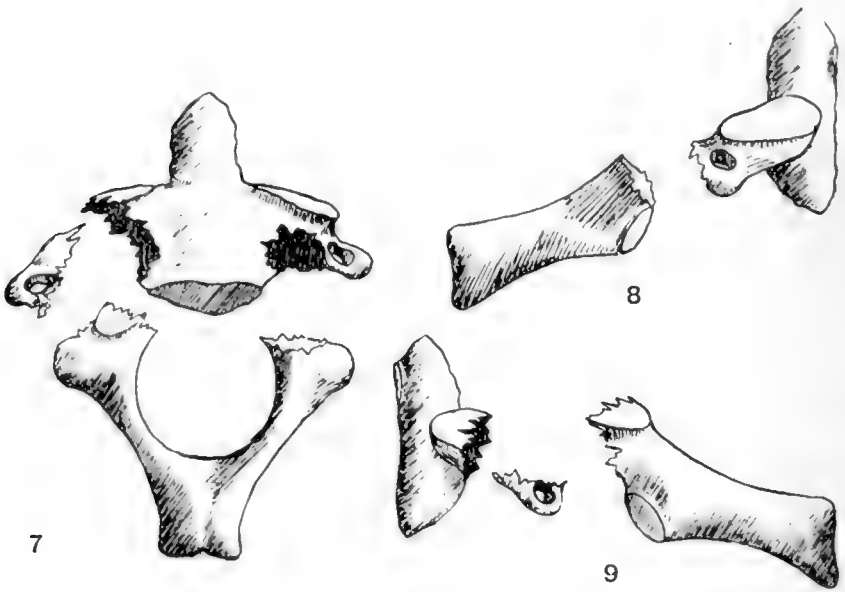

Fig. 7 Body and neural arch of the vertebra.
Fig. 8 Portions of vertebra viewed from the right side.
Fig. 9 Portions of vertebra viewed from the left side.

In the fourth case (figs. 10, 11, 12) the articulations and the condition of the transverse ligament of the atlas were again exactly similar to the previous three cases, the break on the right-hand side was also similar. On the left-hand side the break varied again; this time the break was through the costal element of the transverse process, through the foramen transversum and through the posterior part of the superior articular

surface. In addition to this, it was found that the atlas was also mutilated, the transverse process being broken off from the lateral mass, the fracture being through the roots of the transverse and costal elements. The transverse process itself was also broken into three pieces.

In Gray's Anatomy, page 358, we find the following statement:

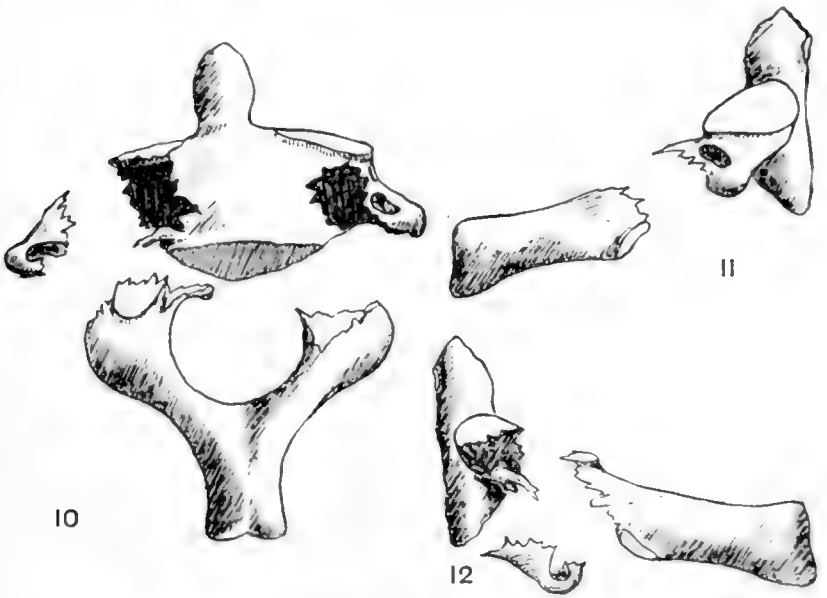

Fig. 10 Body and neural arch of vertebra.
Fig. 11 Portions of vertebra viewed from the right side.
Fig. 12 Portions of vertebra viewed from the left side.

Dislocation of the occipital bone from the atlas has been recorded only in one or two cases; but dislocation of the atlas from the epistropheus, with rupture of the transverse ligament of the atlas, is much more common: it is the mode in which death is produced in many cases of execution by hanging.

From this it appears that rupture of the transverse ligament is a fairly ordinary procedure, especially in cases of death due to judicial hanging. On examination, however, of four cases of

death by hanging it was found that not only was the transverse ligaments of the atlas not ruptured, but there was not the faintest sign of a rupture, the whole ligament was intact, including even its attachment to the atlas; the dens of the epistropheus being held as though it were the true body of the atlas.

Treves and Keith, in their "Surgical Applied Anatomy," page 645, say:

> In the atlanto-axial region the amount of displacement that follows upon luxation of the two bones from one another is such that the cord is, as a rule, severely crushed, and death ensues instantaneously, as is seen in cases of death by hanging.

The crushing of the spinal medulla is here also evidently attributed to the odontoid process.

It may be that occasionally the transverse ligament ruptures on hanging and that under these circumstances the cord is crushed and causes instantaneous death, but in these cases the ruture is most likely due to congenital weakness of the transverse ligament or perhaps to a pathological condition of the transverse ligament or atlas. In the cases of the four well-built young colored men, it is not possible to ascribe death to rupture of the transverse ligament.

Death would be largely due to rupture of the cord, which is allowed for by the downward dislocation of the third cervical vertebra from the second. It is difficult to say where the rupture actually takes place, for the specimens were examined long after the postmortems had been held. To what other cause instantaneous death can be due is difficult to say, as crushing of the cord, as mentioned by Treves and Keith, does not seem very probable, for nothing projects into the canal. The elasticity of the transverse ligament may allow for an instantaneous, slight protrusion of the odontoid process into the neural canal, but this small amount can be compensated for by the fact that the cord is suspended in the neural canal. It is difficult to say what part the fracture of the epistropheus plays. Perhaps this also aids in the crushing of the cord.

In addition to the probable rupture of the cord, one must also take into account the rupture of the big blood-vessels of the brain and vertebral arteries in addition to shock and the rupture of several of the muscles of the neck, such as the M. sternohoideus, M. omohoideus, and others, as well as the possible rupture of the carotid arteries.

Resumen por el autor, Paul E. Lineback,
Universidad Emory, Atalanta, Georgia.

Un caso de polidactilia en un embrión de 22 mm.

El caso presentado en este trabajo, si el autor está bien informado, es el más jóven mencionado hasta el presente, debiendo su significación principalmente a este hecho. Además susministra datos adicionales intesantes sobre el problema del primer hueso metacarpiano y sobre el problema más general del polidactilismo. En este caso el autor encuentra, sin embargo, pocas pruebas concluyentes en favor de las teorías relacionadas con ambos problemas. El único punto valioso que el autor puede ofrecer es que el presente caso lleva el problema del polidactilismo desde el catálogo de los factores causativos extrínsecos al dominio de los factores formativos tempranos.

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED
BY THE BIBLIOGRAPHIC SERVICE, FEBRUARY 7

A CASE OF UNILATERAL POLYDACTYLY IN A 22-MM. EMBRYO

P. E. LINEBACK

Emory University School of Medicine

ONE FIGURE

In the laboratory of the author there is an embryo 22 mm. in length, with an extra digit on the right hand at the base of the metacarpus of the thumb. It was noted by Doctor Streeter while making measurements of the embryo, and he marked it as being, from all available records, the youngest case thus far discovered. This fact seems to warrant the author in making a study and report of it, with a brief survey of the literature on the subject.

The embryo came into the laboratory without data as to its parents or details of its appearance. It has a crown-rump length of 22 mm. and is well formed in every detail, with membranes in normal state. The two hands are similar in every respect, except that the thumb on the right hand is a trifle smaller than the left thumb. The breadth of each hand, midway across the palm, is 2 mm., and the length, from a line across the wrist just back of the thenar eminence to the tip of the middle finger, is 2.5 mm. The right thumb is 1.1 mm. long and 1 mm. thick. Attached to the base of its metacarpus is the extra digit. It stands out from the surface at right angles and is uniform in size and shape. Near the tip it bends slightly forward and terminates in a blunt rounded point. It is 1 mm. long and 0.6 mm. thick. Serial cross-sections were made of the whole forearm and hand beginning at the tip of the fingers and going to the elbow. The sections were cut 10μ thick after staining the specimen in toto in cochineal.

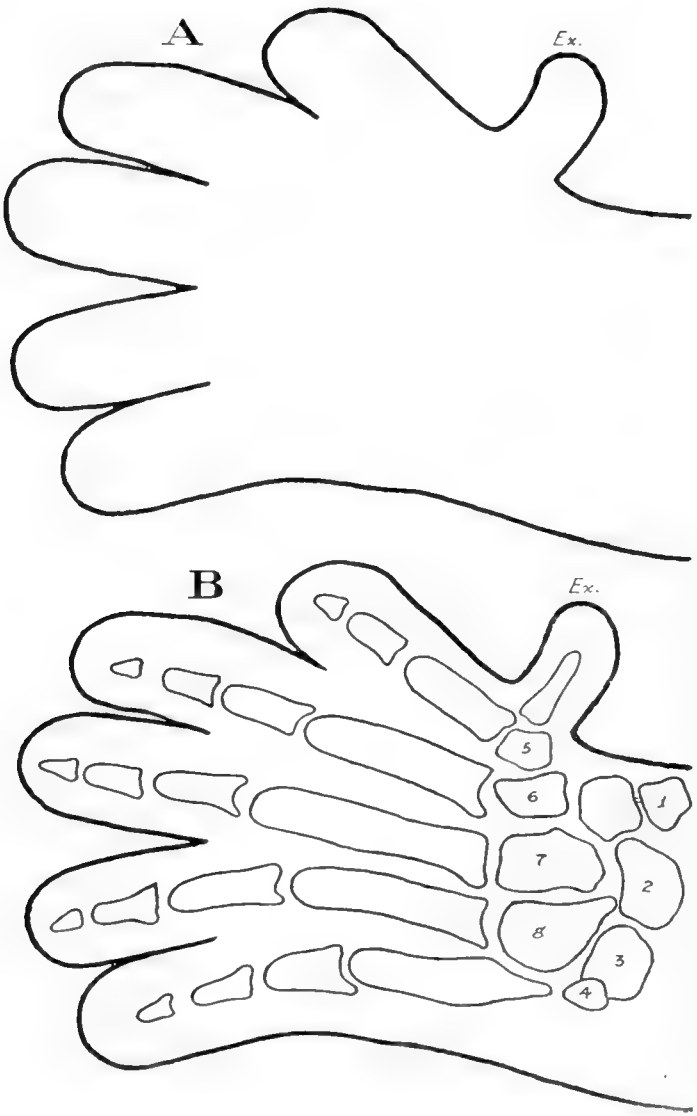

Fig. 1 Outline drawing from reconstructed model. × 22. A. Surface view showing position of extra digit. B. Cartilaginous skeleton showing relationship of extra digit to other skeletal units

Microscopic study shows the cartilages of the wrist, hand, and fingers present. All the separate units of the parts are in place and are still in process of cartilage formation. Each piece shows a peripheral zone of condensed cells beginning to show the features of a perichondrium, and a central core characterized by a network of hyaline strands, in the meshes of which may be seen large cartilage cells. The skeleton of the extra digit is a single piece of cartilage having the above characteristics. It is a separate unit with close relationship to the base of the metacarpus, and not an offshoot or spur from it.

Two muscles are contained in the digit, a volar and a dorsal muscle. The one on the dorsal side extends through the mesenchyma out toward the tip, but ending short of it. Its origin and identity are uncertain; probably it comes from the outer head of the first dorsal interosseous muscle. The volar muscle can be more certainly identified. It arises from the abductor policis brevis and extends to near the tip of the digit on the palmar side. Nerves cannot be identified and vessels are seen only as undifferentiated capillaries.

In going through the literature, no cases are cited of polydactyly in the young embryo; all are late foetuses or postnatal cases and the majority are in adult life. Salzer ('98), reporting two cases of triple phalangeal thumbs, opened the question as to which phalanx is missing in the ordinary thumb, the end phalanx or the middle phalanx. He quoted Windle, who made a general summary of such cases by expressing the opinion, with some reservations, that the extra phalanx must have occurred from the fact that the distal bone center of the first metacarpus developed independently. He referred to Uffelman's work, in which it is shown that at the capitellum of the first metacarpus a special bone center is present without ever existing independently. He thinks that this extra center may give rise to a supernumerary phalanx, which would be the main phalanx. Salzer quoted Pfitzner also, who seemed to hold that a triple phalangeal formation is, for a brief period, a normal state and that the double phalangeal thumbs and toes have come about in this manner, from the merging of the middle and end phalanges

gradually a typical and enlarged phalanx has resulted. In support of this he cites a case of a girl with a strikingly large end phalanx consisting of two pieces which have not been completely fused. Jurcic ('06) reported a case of hyperphalangea in both thumbs. In this report he took up the problem of whether the thumb should be considered as possessing normally three phalanges and no metacarpus, or a true metacarpus and only two phalanges. He cites the fact that the first bone of the thumb develops in the same manner as the phalanges, the head and shaft from a common primary center, and the base from an epiphysis. The development of the metacarpals is just the reverse, the base and shaft arise from a common primary center and the head from an epiphysis. He concludes, however, that from the manner of muscle attachment to the first metacarpus and noting the presence of the extra ossification center in some mammals, and occasionally in man, this is a true metacarpus and not a basal phalanx.

Stieve described a case of bilateral hyperphalangea ('15–16) and quoted Krause ('09), who objected to Pfitzner's work on the ground that it dealt with malformations, which was poor material for drawing such conclusions. In Stieve's case the end phalanx, which should be shorter than in normal diphalangeal thumbs, is especially long, and in Salzer's cases the two end phalanges show no proportionate shortening. He finds also that whereas there was restricted movement between the end and middle phalanges of Hilgenreiner's case, the movement in his case was especially free. Backed by these points, he comes to the conclusion, differing with his predecessors, that the end phalanx in the diphalangeal thumb is not a fusion of the middle and end phalanges. He seems to hold to this opinion more firmly when he notes that we are not dealing with perfect triphalangeal thumbs in reported cases, but the extra piece is only the radial side of the middle phalanx.

Hilgenreiner apparently has the most complete list of cases of hyperphalangeal thumbs and the most valuable data concerning the subject. According to him, 107 three-jointed thumbs, fifty-eight cases, had been noted to date ('10). He goes to

some length in discussing the condition and makes a definite classification of the cases. In the first class he would include cases where there is only partial separation of the end and middle phalanges—incomplete hyperphalangea. In class 2 he would include only such cases as show complete formation of the middle phalanx having a diaphysis and an epiphysis true hyperphalangea. In these cases the thumb characteristics have been lost and the structure is more like an extra index-finger. This change of characteristics is proportionate to the degree of separation of the phalanges. He is quite firm in his opinion that the condition of diphalangeal thumb has arisen from a fusion of the end and middle phalanges in early stages of formation. He sees two possible explanations in these cases of anomalous thumbs, but does not pursue either at length. He speaks of a palingenesis of the middle phalanx traceable to some endogenous cause. This factor is mentioned by others also, Minoura and Prentiss. He also states that the supernumerary phalanx is not always to be explained as a palingenesis of the middle phalanx, since it may arise from the epiphysis of the second phalanx. In such cases triphalangeal thumbs appear only postpartem in the first, second, or third year of child life.

Prentiss ('03) has contributed to the subject a valuable piece of work, dealing with it in a somewhat broader fashion than Hilgenreiner, although his study of cases in man, especially of thumb variations, is rather too limited for valuable application here. He states that "variations are found chiefly in digits which are modified, rudimentary or vestigial." As to the causes of polydactyly he has this to offer: "in man it is not a definite number of extra digits but a tendency to duplication which is inherited" and "duplication of functional digits is probably caused by germinal variations alone."

After reviewing the above literature, which is, although brief, a general and inclusive statement of opinions on the subject, several problems present themselves or at least several aspects of the same problem. There appears to be a difference between hyperphalangea and polydactyly. The former is characterized by the presence of an extra phalanx, with the main disfiguration

of the thumb an increase in its length or a deflection to the ulnar side. The latter is marked by the presence of an extra digit, either large or small, fully formed or rudimentary, which stands apart from the other digits. The problem of di- and triphalangeal thumbs, as to how the normal thumb should be regarded and the origin of the extra phalanx in triphalangea, comes under the head of hyperphalangea. Here would be placed the cases of Jurcié, Salzer, Stieve, and some of Hilgenreiners. Under polydactyly would be included such cases as Prentiss', others of Hilgenreiner's, and the author's.

Another point is that variations in the thumb should be considered in a special class apart from variations in the other fingers, since here is found, in the normal state, a condition unlike that in the others.

Prentis's statement that, "variations occur chiefly in digits that are modified," would lend emphasis to this, and Hilgenreiner seems to have considered it worth while to tabulate over one hundred cases of thumb variations.

Standing out prominently among these points is the problem of the causative factor in polydactyly and hyperphalangea, and how this factor operates. Upon this point the author's case presents some features, not noted in others, which might be considered a little more at length. Here is a clear case of polydactyly having an extra digit with a separate piece of cartilage. All the other units of the wrist and hand are present but still in the cartilaginous state. It is conclusive that the causative factor of splitting of a digit by an amnionic band is not operative here. Nor is the factor of an extra phalanx arising from a diverted center of ossification to be applied, since the digit is present before ossification appears anywhere in the hand. The specimen permits of an investigation further back than the beginning of ossification. Here might be applied the theory of palingenesis as suggested by Minoura, Hilgenreiner, and Prentiss, although the last author might not include it here. Or again, Prentiss' reversion to a not remote ancestral form, an inheritance, working through Mendel's law, might be applied. He states that "all cases of polydactyly, not due to external

causes, may be the result of inheritance." These two theories presuppose a parental state from which they may work, and the natural question arises as to what caused the first deviation in the original parent. 'Germinal variation' is an expression commonly used by investigators and especially by Prentiss when he says, "but the duplication of functional digits are probably caused by germinal variation alone." He further states that, "as to the cause of these germinal variations . . . . we know little or nothing." In his comprehensive work, "Science and philosophy of the organism," Driesch put the essence of the matter in a more concrete form when he gave expression to 'feeling for form.' Just how far these expressions are usable is a question; they at least emphasize the fact that search must be made in the field of cytology and cytochemistry in dealing with the state of abnormal thumbs.

CONCLUSIONS

The author feels justified in drawing the following conclusions:

1. Hyperphalangea and polydactyly are sufficiently different to be put into separate classes.

2. The thumb offers sufficient significance to warrant separate study in its variations.

3. The author's case offers proof that some cases of polydactyly owe their origin to earlier causes than external factors or deviation of ossification centers.

Resumen por la autora, Helen Dean King.
The Wistar Institute of Anatomy and Biology.

Un estudio comparativo de la mortalidad durante el nacimiento en la rata albina y en el hombre.

Los datos reunidos durante un periodo de cinco años demuestran que en un total de 31,670 ratas albinas recién nacidas, 415, o sea el 1.3 por ciento, nacieron muertas. Concediendo que hay probablemente error en estos cálculos, la mortalidad normal durante el nacimiento en la rata albina es de unos 2 por ciento, esto es la mitad de la misma mortalidad en el hombre. En ambas especies la relacion normal de los individuos nacidos con vida es próximamente de unos 105.5 machos por cada 100 hembras; en los nacidos muertos esta relación aumenta hasta ser de 130 machos por cada 100 hembras. La mortalidad postnatal es un poco mayor que la mortalidad durante el nacimiento tanto en la rata como en el hombre.

Las causas a que debe atribuirse cerca de la mitad de los nacimientos de individuos muertos en el hombre, esto es las enfermedades infecciosas, implantación defectuosa y obstrucción mecánica durante el nacimiento, al parecer no influyen sobre la mortalidad natal de la rata. Las causas principales de tal mortalidad en dicho animal parecen ser los factores que afectan la nutrición del feto, tales como la edad y condición física de la madre, lactancia y número de individuos de la cría. Tanto en la rata como en el hombre, el feto macho parece ser intrínsecamente más débil que el hembra, y por consiguiente puede ser influído adversamente con más facilidad por las condiciones inímicas al desarrollo normal. La autora propone una hipótesis que supone que la diferencia en el vigor constitucional de ambos sexos depende de la estructura diferente de la cromatina en el zigoto macho y en el hembra.

AUTHOR'S ABSTRACT OF THIS PAPER ISSUED
BY THE BIBLIOGRAPHIC SERVICE, DECEMBER 27

A COMPARATIVE STUDY OF THE BIRTH MORTALITY IN THE ALBINO RAT AND IN MAN

HELEN DEAN KING

The Wistar Institute of Anatomy and Biology

Literature dealing with birth statistics for man contains numerous references both to the number and to the sex of the stillborn; but in none of this literature, nor in any of the many works covering various phases of animal breeding, is there any detailed information regarding birth mortality in other mammals. It has seemed worth while, therefore, to record the data for stillbirths in the albino rat that have been collected in the course of an extensive series of breeding experiments carried on in the animal colony of The Wistar Institute of Anatomy and Biology. Life processes in the rat accord in many ways with those for man, as Donaldson ('06, '08, '18) has pointed out, and the data given in the present paper indicate that there is also a close agreement in their normal sex ratio, in their birth mortality, and in the sex proportions of the stillborn.

The collection of data regarding the birth mortality in the albino rat was begun June 1, 1913, and carried on uninterruptedly for four years; it was resumed the beginning of June, 1918, and discontinued June 1, 1919. In any investigation of this character it is essential that all of the individuals in a given litter should be recorded, if the data are to have much statistical value. This necessitates, in the case of the rat, an examination of the litters at birth, or shortly after, since stillborn young left for a longer time in the nest are sometimes destroyed. While it is known that the data for the great majority of litters included in this study are complete, there is a probability that some of the stillborn young were omitted from the records, since all litters could not be examined at or close to the time of birth. The magnitude of the probable error is not great enough, however, to affect

the general conclusions that have been drawn, though more exact data might change somewhat the various percentages given.

Normally, young rats begin suckling soon after their birth, and as at this time and for some days afterward the skin over the abdomen is semi-transparent, any milk in the intestinal tract is readily seen and is a sure indication that the individual was alive when born. There is, therefore, no difficulty in distinguishing the stillborn individuals from those that died later, even though the litter is not examined until a day or two after it is cast. Throughout this paper the word 'stillborn' is applied only to young rats that lived through the normal gestation period (twenty-one to twenty-three days) and died shortly before or during birth, and the mortality data given are for such individuals only. Only a very few cases of abortion have been found in the course of breeding experiments with the rat extending over a period of eleven years and comprising many thousands of individuals; none of these are included in the present study.

THE NORMAL PERCENTAGE OF STILLBIRTHS

During the period in which the birth mortality statistics for the albino rat were being collected, a total of 253 litters were found in which one or more individuals were stillborn. Data for these litters, arranged according to the year in which the records were taken, are given in table 1.

The data given in table 1 show that there was considerable variation in the number of stillbirths occurring in different years. Such variation was to be expected, since the total litter production in the colony varied greatly from year to year (table 2). The percentage of stillbirths in the total number of individuals involved, however, is remarkably constant for all sets of data, as the range of variation is from 20 to 26.2 per cent only (table 1). Since in each year that records were taken at least one-fifth of the young in a considerable number of litters were dead at birth, it is evident that the mortality was not due to chance, but to some disturbance in the metabolism of the mother that tended to involve the litter as a whole.

In order to show the normal percentage of stillbirths in the entire colony, data for the total litter production during the period that the mortality records were taken are given in table 2.

TABLE 1

Data for living and for stillborn young in 253 litters of albino rats. Groups arranged according to the year in which the records were taken

YEAR	NUMBER OF LITTERS	TOTAL NUMBER OF YOUNG	LIVING YOUNG			STILLBORN YOUNG			
			Males	Females	Number of males to 100 females.	Males	Females	Number of males to 100 females	Per cent stillborn in total number of young
1913–1914	29	225	81	99	81.8	25	20	125.0	20.0
1914–1915	78	570	222	225	98.7	70	53	132.1	21.6
1915–1916	35	289	121	104	116.3	36	28	128.6	22.1
1916–1917	51	339	135	115	117.4	48	41	117.1	26.2
1918–1919	60	394	152	148	102.8	55	39	141.0	23.8
	253	1,817	711	691	102.9	234	181	129 3	22 8

TABLE 2

Showing the total number of individuals, including the stillborn, that were produced in a colony of albino rats during a period of five years

YEAR	TOTAL NUMBER OF LITTERS	TOTAL NUMBER OF INDIVIDUALS	MALES	FEMALES	NUMBER OF MALES TO 100 FEMALES	NUMBER OF STILLBORN	PER CENT STILLBORN
1913–1914	899	6,677	3,379	3,298	102.5	45	0.67
1914–1915	945	7,065	3,690	3,375	109 3	123	1 74
1915–1916	828	6,443	3,273	3,170	103 2	64	0 99
1916–1917	1,023	7,131	3,597	3,534	101.8	89	1.25
1918–1919	625	4,354	2,217	2,137	103.7	94	2.16
	4,320	31,670	16,156	15,514	104.1	415	1 31

As table 2 shows, from 600 to 1000 litters of albino rats were born each year during the period covered by the investigation. The percentage of stillbirths in the total litter production varied considerably in different years, and for the 31,670 births was 1.31 per cent. Assuming, for reasons to be given later, that at most only 8 per cent of the stillbirths that occurred were not recorded, it would appear that the normal birth mortality in the colony, under existing conditions of environment and of nutrition, was not greater than 2 per cent.

During the past seventy-five years an extensive literature has appeared dealing with the birth statistics for man in various countries of the world. From the data given in this literature, Nichols ('07) has compiled a table showing the living and the stillbirths throughout the world during the period from 1751 to 1903. In the enormous total of 447,019,579 births recorded, 13,635,986, or 3.04 per cent, were stillbirths. From a statistical standpoint the various sets of data used by Nichols are not of uniform value, since the laws regarding the registration of births vary greatly not only in different countries, but in different sections of the same country (as in the United States), and therefore many of the records are known to be incomplete. The records of stillbirths, especially, are very faulty, partly because in many countries their registration is not required and partly because the data obtained include fetuses aborted at various stages of gestation. With reference to human births, it may be noted, the word 'stillborn' is used to designate fetuses that are at least seven months of age when born; fetuses aborted at earlier stage of development are not ordinarily included in birth statistics.

More recent series of statistics show a birth mortality for man varying but slightly from that given by Nichols. Thus Auerbach ('12) states that in over 100,000 births as registered in Budapest, 3.3 per cent were stillbirths, and Terry ('17) has shown that in a total of 449,744 births recorded in Massachusetts during 1910 to 1914 there were 15,911, or 3.2 per cent, of stillbirths.

In certain countries in which the laws regarding the registration of births are relatively strict, the percentage of stillbirths is somewhat higher than that given by Nichols. For example, statistics for Prussia during the period from 1872 to 1881 show, according to Düsing ('84), that the stillbirths formed 4.67 per cent of the total of 10,577,478 births; birth statistics for the United States during 1918 show 3.56 per cent of stillbirths in a total of 1,412,283 births (Davis, '20).

The data for human births in one year in selected cities of the United States, as collected by The Children's Bureau of the U. S. Department of Labor, form a unique and valuable series (Duke, '15; Duncan and Duke, '17; Allen, '19; Dempsey, '19). Although

the number of births recorded is very small when contrasted with the large numbers given above, the great care taken to make these records as complete as possible gives to the data great statistical value.

Birth statistics for four selected cities, as collected by The Children's Bureau, are given in table 3.

TABLE 3

Summary of human births in one year based on data collected by the U. S. Children's Bureau in selected cities of the United States. 1, Brockton, Mass.; 2, Johnstown, Pa.; 3, Manchester, N. H.; 4, Saginaw, Mich.[1]

	TOTAL NUMBER OF BIRTHS	NUMBER OF MALES TO 100 FEMALES	LIVING YOUNG				STILLBORN YOUNG				
			Number of individuals	♂	♀	Number of males to 100 females	Number of individuals	♂	♀	Number of males to 100 females	Per cent stillborn in total number of young
1	1,247	105.77	1,210	623	587	106.13	37	18	19	94.73	2.96
2	1,551	110.16	1,463	761	702	108.40	88	52	36	144.44	5.67
3	1,643	101.10	1,564	781	783	99.74	79	45	34	132.35	4.80
4	1,015	107.99	981	507	474	106.92	34	20	14	142.85	3.34
	5,456	105.96	5,218	2,672	2,546	104.94	238	135	103	131.06	4.36

[1] Statistics of births during one year in a fifth city, Waterbury, Conn., have also been published by the Children's Bureau (Hunter, '18). The data given show a total of 2,654 births of which 3.2 per cent were stillbirths. Since sex data are given for only 53 of the 86 stillborn young, this series of data is excluded from table 3.

As shown in table 3, the percentage of stillbirths in the various cities concerned varied from 2.96 (Brocton) to 5.67 (Johnstown), and in the total of 5,456 births recorded there were 238, or 4.36 per cent, of stillbirths. In this series, therefore, the birth mortality is considerably higher than that in any series of data previously cited, yet in each of the papers in which the birth statistics are given it is stated that the number of stillbirths recorded is probably too low, owing to the great difficulty experienced in obtaining accurate information regarding such births. It has been estimated that at least 5 per cent of stillbirths are never recorded, even in localities in which the laws regarding their registration are most rigidly enforced.

Although the birth mortality in domestic animals would seem to be a matter of considerable importance to the stock breeder, there are only a few scattered references to it in works dealing with various phases of stock breeding, and practically no data having statistical value are available for analysis. According to Bernoulli ('41), records for Europe covering a period of ten years show that from 10 to 15 per cent of calves were dead at birth. As, however, a very great proportion of these deaths were undoubtedly abortions due to infectious disease, the normal birth mortality among full-term fetuses is yet to be determined.

Fairly complete records regarding living foals have been kept in various studs throughout Europe for many years, but data for the stillborn are very meager. Records compiled by Hoffman ('85) show that in a total of 1,556 foals, 87, or 5.6 per cent, were stillborn: Goehlert ('84), quoting Baumeister, states that on the average 6 per cent of all foals are born dead: 4 per cent of these are cases of abortion and 2 per cent are of foals at the end of term. In neither of these papers are any data given that show the sex proportions among the stillborn young.

Available evidence thus seems to indicate that in the higher mammals from 2 to 4 per cent of full-term fetuses are dead at birth, and it is probable that at least half of this mortality is due either to disease or to mechanical injury at birth.

THE SEX RATIO IN STILLBORN YOUNG

It is a matter of considerable interest whether the sex ratio, i.e., the number of males to each 100 females, in the stillborn is the same as that in the living young. For if there is a pronounced and constant difference between these two ratios, there must be some disparity between the sexes that is an important factor in the birth mortality.

In order to make possible a comparison between the sex ratio for the living and that for the stillborn young of the albino rat, it is necessary to ascertain the sex ratio that is normal for the species. Cuénot ('99) gives 105.6 males to 100 females as the sex ratio in thirty litters of albino rats; records for over 1000 litters of stock Albinos, as collected by King and Stotsenburg ('15),

show a sex ratio of 107.5 males to 100 females; while the data as given in table 2 of the present paper indicate a sex ratio of 104.1 males to 100 females in a total of 31,670 births.

The normal sex ratio for any species can be obtained only by ascertaining the sex proportions among all of the offspring of a considerable number of females kept under favorable conditions of environment and of nutrition during the entire period of their reproductive activity. None of the sex ratios for the albino rat as given above can, therefore, properly be taken as the norm, since none of them are based on completes series of data. Records covering the complete breeding history of a number of stock albino females have recently been obtained, however, and they show that the sex ratio in the newborn, including those dead at birth, is about 107 males to 100 females.* This ratio, therefore, is the one that will be taken as the norm for comparison with the sex ratio in the stillborn.

On referring to table 1 it is found that in each year that mortality data for the albino rat were recorded there was a very great excess of males among the stillborn. While the number of stillbirths in any year was relatively small, the fact that in each set of records the sex ratio varies from the norm in the same direction and to a very considerable degree adds materially to the value of the data. In the total of 415 stillbirths recorded the sex ratio was 129.3 males to 100 females. This ratio is 26 points above that for the living young in the litters concerned, and as it is 22 points higher than the sex ratio taken as the norm (107 males to 100 females) the deviation is much too great to be considered as within the limits of normal variation. Granting that the records for stillbirths are incomplete, there is no reason to suppose that the sex ratio in the unrecorded stillborn would differ materially from that for the recorded stillborn as given in table 1. The evidence at hand, therefore, indicates that in the rat the mortality at birth is far greater among the male than among the female young.

According to Rauber ('00), as early as the year 1660 Graunt showed that more boys than girls were born in the city of London, and this finding has been confirmed by practically every collector

of human birth statistics since that time. Nichols' very comprehensive table of birth statistics, to which reference has already been made, shows a sex ratio of 105.5 males to 100 females in over four hundred million living births. More recent data give practically this same ratio: thus data for 171,297 living births of white and colored children in Cuba during the period from 1904 to 1906, as given by Heape ('09), show a ratio of 105.46 males to 100 females; while among the 465,655 births in Massachusetts from 1910 to 1914 the sex ratio is 105.41 males to 100 females (Terry, '17). Statistical evidence from many different sources thus seems to warrant the conclusion that in all civilized countries of the world there is an excess of males among the living young; the ratio which may be considered as the norm being about 105.5 males to 100 females. This ratio, as several investigators have pointed out, is remarkably constant and is maintained "through periods of war and of peace, of famine and of plenty, and under a great variety of racial and of climatic conditions; the variations, as a rule, being not greater than one per cent" (Pike, '07).

Available statistics for the sex of stillborn children are admittedly very incomplete, yet millions of such births have been recorded and they invariably show a fairly uniform sex ratio that differs in a marked degree from the sex ratio which is the norm for the living young. A few series of investigations may be cited to indicate the trend of such statistics in general. In the 13,635,986 stillbirths compiled by Nichols there were 131.6 males to each 100 females, the range of variation in the number of males being from 130 to 140 in the great majority of cases. In the records for stillbirths in various countries of Europe, as tabulated by Lewis and Lewis ('06), the number of males to 100 females varies from 120 to 170, with the average around 130; Heape's ('09) data for Cuban births shows a sex ratio of 144.45 males to 100 females among the stillborn, while Hirsch ('13) gives 127.9 as the number of males to 100 females in the stillborn young recorded in Germany during 1908 to 1909; and, finally, the birth statistics of the United States for the year 1918 indicate a sex ratio of 137.1 males to 100 females among the stillborn (Davis, '20).

All of the various series of records given above show that the sex ratio in the stillborn is much higher than that in the living young, and sex statistics for aborted fetuses indicate that the excess of boys becomes greater the earlier the month of pregnancy in which the fetus dies (Rauber, '00; Nichols, '07; Auerbach, '12; Carvallo, '12). This latter fact is of great importance, since it indicates that one, at least, of the chief causes for the excessive mortality among males at birth must be sought in conditions that exist in early rather than in late stages of gestation.

In 1841 Bernoulli called attention to the fact that the sex ratio at birth is not the ratio in which the young are conceived, and he concluded that the true sex ratio for man is about 108.2 males to 100 females. This ratio is practically the same as the 'primary' sex ratio recently calculated by Jendrassik ('11) and by Schultz ('18). The fact that in man the sexes are very evidently not conceived in equal numbers is a decided stumbling-block in the way of any theory of sex determination that postulates chance as the chief factor in deciding whether a given ovum shall become male or female. Morgan ('19) has recently offered the following explanation for the constant sex ratio in man:

> Since male babies die oftener than females, the difference has been said to be an 'adaptation,' with the implication that it calls for no further explanation. Several possible solutions suggest themselves. The male-producing sperm bearing the sex-chromosome may more frequently develop abnormally than the female-producing sperm. Again, since the spermatozoa must, by their own activity, travel the entire length of the oviduct to reach the egg as it enters the tube, the greater size or weight of the female-producing sperm may give a slight advantage to the male-producing sperm in the long trip up the tube. This would lead to an excess of males.

Since there is no evidence at present that one kind of spermatozoa is more active or more inclined to be abnormal than the other, it must be admitted that the above explanation for the male excess in human offspring is not an entirely satisfactory one.

A comparison of the sex ratios found in the newborn of the rat with the corresponding ones for man show that they agree closely in all cases. The sex ratio that is normal for the living young at birth is practically the same in both species, being about 105.5

males to 100 females; in both species, also, the sex ratio in the stillborn is much higher than that in the living young, averaging about 130 males to 100 females. This striking similarity in the sex ratios of two such widely separated mammals as the rat and man is a matter of considerable theoretical interest, and it may have a practical bearing as well, since through carefully controlled experiments on the lower form it may be possible to obtain information that will help to check the appalling birth mortality among human offspring.

Although a considerable body of statistics has been collected by Düsing ('84) and by Wilckens ('86), among others, regarding the normal sex ratio in domestic animals, practically no information is available concerning the sex proportions in the stillborn. In fact, the only reference to this subject that I have been able to find is in a paper by Goehlert ('82) which deals chiefly with the inheritance of coat color in the horse. Goehlert states that in 135,826 living foals born in various studs throughout Europe the sex ratio was 96.57 males to 100 females. Then follows this significant statement: "Derselbe steigert sich bei den todtgeborenen auf 106 bis 107 Hengst gegen 100 Stutenfohlen." The data on which the above statement is based are not given, but if they are extensive and accurate enough to have statistical value, they indicate that the sex ratio in stillborn foals is some 10 points higher than that in living foals. Thus in man, in the rat, and in the horse, the only mammals for which data are at present available, the birth mortality is apparently far greater among the male than among the female young. It is not improbable that future investigations will show that this condition is characteristic of the Mammalia generally.

SEASONAL VARIATIONS IN THE PERCENTAGE OF STILLBIRTHS

It has been claimed by Düsing ('84) that seasonal variations in temperature, through their action on nutritive conditions, affect not only the sex of developing fetuses, but the percentage of stillbirths as well.

The desirability of recording data for stillborn rats according to the month of the year in which birth occurred was not realized

when this investigation was begun, consequently only the data collected during the last year can be grouped by seasons as shown in table 4.

Stillbirths were recorded in the colony during every month of the year, the smallest number (3) being found in May, the largest (14) in September. On grouping the data as shown in table 4, it is seen that the 94 stillbirths were very evenly distributed throughout the different seasons, the variation in number being from 21 (spring) to 25 (autumn). The percentage of stillbirths in the total litter production, however, shows a wide range of variation in different seasons, being nearly twice as great in

TABLE 4

Showing the percentage of stillbirths in the albino rat colony from June 1, 1918, to June 1, 1919. Data arranged according to the season of the year in which birth occurred

SEASON	TOTAL NUMBER OF LITTERS	TOTAL NUMBER OF YOUNG	NUMBER OF STILLBIRTHS	PERCENTAGE STILLBIRTHS IN TOTAL NUMBER OF YOUNG
Spring (March to May)	183	1,349	24	1.78
Summer (June to August)	166	1,134	21	1.85
Autumn (September to November)	120	821	25	3.04
Winter (December to February)	156	1,050	24	2.28
	625	4,354	94	2.16

autumn (3.04) as in summer (1.78). The data given in table 4 are, of course, too few to have much statistical value, but they seem to indicate that the percentage of stillbirths tends to vary somewhat with the season, reaching its highest point in the autumn months. Lacking adequate means of heat regulation, rats suffer severely from high temperature, and the young born late in summer and in the autumn are, as a rule, inferior to those born at other seasons as regards their power of growth, resistance to disease, fertility, and longevity. It is not surprising, therefore, to find that this lowering of the physical tone of the animals at a definite season of the year is followed by an increase in the birth mortality.

From an analysis of the data for over ten million births occurring in Prussia from 1872 to 1881, Düsing ('84) concludes that "bei den Kindern, welche im Anfang des Jahres erzeugt und im Herbst geboren werden, zeigen sich die wenigsten (3.6 per cent), dagegen bei denen, welche im Frühjahr gezeugt und in Winter geboren werden, die meisten tot-geburten (4.4 per cent)." Other groups of statistics for human births do not support Düsing's conclusions, however, Thus, data compiled by Davis ('20) show that in the birth registration area of the United States during 1918 the lowest percentage of stillbirths occurred during the summer (3.07 per cent), and the highest in the autumn (3.79 per cent); while birth statistics for the city of Philadelphia covering a period of ten years (Sozinskey, '85) and also those for Boston during 1891 to 1910 (Whipple, '19) indicate no appreciable variation in the rate of stillbirths during different seasons of the year.

From available evidence it would appear that the birth mortality in man is but little influenced by the season of the year in which either conception or birth occurs. Since man has a highly developed mechanism for heat regulation, moderate changes of temperature have very little effect on body metabolism and therefore cannot, under ordinary circumstances, influence the nutrition of the fetus, as Düsing claims.

POSTNATAL MORTALITY

Since deaths that occur among the young within a few days after birth are traceable, in many cases, to prenatal causes that are responsible for a certain proportion of stillbirths, a brief consideration of postnatal mortality is included in the present paper.

Little exact information is available, as yet, regarding the mortality among young rats during the week after birth. The number of such deaths in any large colony is considerable, but what proportion of them is due to prenatal causes cannot be determined, since a great part of such mortality is always due to causes that are purely accidental, such as smothering of the young by the crowding of adults into the nest when they are cold or

frightened and death from exposure or starvation when the young leave the nest and are not carried back by the mother.

Records kept from June 1, 1918, to June 1, 1919, show that ninety-eight rats died within three days after birth from causes that were undetermined. As during this year 4,250 living young were born in the colony, the postnatal mortality was 2.3 per cent. or slightly greater than the birth mortality during the same period (table 2). Although the great majority of these deaths were undoubtedly accidental, some of them were unquestionably due to prenatal causes that so affected the constitutional vigor of the individual that death was inevitable. Occasionally litters are cast in which one or more of the members are very much under normal size. These small individuals are the so-called 'runts,' which are frequently found among multiparous mammals, and since they are usually unable to compete with the larger and more vigorous individuals of the litter in their efforts to obtain food, they generally die within a few days after birth. Under very favorable conditions some of these undersized individuals are able to survive and to reach maturity, but they never attain the size of the normal members of the litter and they are usually sterile (King, '16). Since runts are found most frequently in very large litters cast by young females and in litters cast by females that are not in good physical condition, they are evidently individuals with relatively low initial vitality that were subjected to conditions inimical to growth during the intrauterine period; the weaker among them die soon after birth, those that survive are among the physically unfit that generally 'drop out' at a relatively early age.

Among the 98 young recorded as dying shortly after birth there were 42 males and 56 females, or a sex ratio of 75 males to 100 females as contrasted with a sex ratio of 141 males to 100 females in the stillborn young found during the same period (table 1). The marked difference between these two ratios is readily explicable. Factors responsible for the great excess of males among the stillborn can act only to a very limited extent in influencing the sex ratio in the young that die after birth, and postnatal mortality due chiefly to accidental causes might be ex-

pected to take a heavier toll from the females, since at birth the females are somewhat smaller, as a rule, than the males (Donaldson, '06; Jackson, '13; King, '15).

The question of postnatal mortality among human offspring involves so many different factors that an adequate consideration of the subject cannot be attempted here. The many investigations that have been made show that the mortality is very high during the first month after birth, averaging about 5 per cent of all young. About one-fourth of these deaths, it has been estimated, are due to improper care or to disease, the remaining can be attributed to premature birth, injuries at birth, or to congenital debility (Ashby, '15; Hunter, '18; Eastman, '19; Dempsey, '19).

Sex statistics for infants dying under one year of age, as collected by a number of investigators in various countries (Düsing, '84; Rauber, '00; Prinzing, '06; Nichols, '07; Dutton, '10; Pinard et Magnan, '13; Kroon, '17; Ashby, '15; Davis, '18, '19, etc.), all show that infant mortality is considerably greater among boys than among girls, and that, while it varies considerably in different localities and under different conditions, on the average about 120 boys die to each 100 girls.

A comparison of the findings for the rat with those for man shows that in both forms the postnatal mortality is somewhat higher than the birth mortality; in the rat this mortality is chiefly due to accidental causes that seemingly tend to kill more females than males, while in man infant mortality is traceable in many cases to 'congenital debility' which is apparently far more fatal to males than to females.

CAUSES OF BIRTH MORTALITY

Barring accidents, there are six leading causes to one or another of which practically all stillbirths in mammals can be ascribed: 1) malposition of the fetus leading to abnormal development; 2) infectious disease; 3) mechanical obstruction to birth, including size of the fetus; 4) physical condition of the mother; 5) age of the mother; 6) congenital debility. The part played by these various factors in the birth mortality in the rat and in man will be discussed briefly in the following sections.

a. Malposition of the fetus and disease as causes of birth mortality

Faulty implantation is responsible for the abnormal development of many ova in the rat (Huber, '15), but these ova, as a rule, die at an early stage and are absorbed in situ. Little is known, as yet, regarding the death in utero of older embryos. The examination of a number of gravid females indicates that this phenomenon is not as common in the rat as it is in many other multiparous mammals (Stahl and Henneberg, '02; Hammond, '14). So-called 'monsters,' which arise through faulty implantation and consequent inadequate nutrition of the embryo, comprise about 1 per cent of all human fetuses at birth (Mall, '08), but they are very rare among newborn rats. In the course of an examination of over 50,000 young rats I have found but four such fetuses, and in all of these the body appeared perfectly normal, but the head was hydrocephalic.

Infectious diseases are responsible for an appalling number of deaths among human offspring and among the young of cattle, but no cases are known, as yet, in which stillbirths in the rat could be ascribed to this cause. Neither the rat scourge, so-called 'pneumonia,' nor other diseases common to the rat are transmitted to the fetus as far as is known. From the evidence at hand, therefore, infectious disease can be eliminated as a cause of stillbirth in the rat, though illness of the mother, as will be shown later, is a potent factor in birth mortality.

b. The size of the fetus as a cause of birth mortality

Since the size of the fetus is an important factor in human birth mortality (Düsing '84; Nichols, '07; Dutton, '10; Hirsch, '13), it is conceivable that this factor may also play a rôle in the birth mortality in the rat. The following series of observations was made to determine this point.

Fifty-nine litters of rats, in which one or more members were stillborn, were obtained at birth. Each of the young rats was taken from the mother as soon as it was cast, the placenta was removed, and the body weight taken immediately. Data regarding the age and general physical condition of the mother at

the time of parturition were also recorded, since these factors had to be taken into account as possible causes of birth mortality.

The body weight records for the 306 living and for the 137 stillborn young in these fifty-nine litters are shown in table 5. For purposes of later analysis the data are arranged in three groups according to the physical condition of the mother at the time of parturition.

TABLE 5

Sex and body-weight data for living and for stillborn young in fifty-nine litters of albino rats. Groups arranged according to the physical condition of the mother at the time of parturition

GROUP	PHYSICAL CONDITION OF MOTHER	LIVING YOUNG						STILLBORN YOUNG						Percentage stillborn in total number of young
		Number of individuals		Average body weight all individuals		Average body weight largest individuals		Number of individuals		Average body weight all individuals		Average body weight largest individuals		
		♂	♀	♂	♀	♂	♀	♂	♀	♂	♀	♂	♀	
				gms.	*gms.*	*gms.*	*gms.*			*gms.*	*gms.*	*gms.*	*gms.*	
1	Good	68	51	4.57	4.28	4.91	4.52	21	21	4.20	3.75	4.50	4.11	26.1
2	Poor	43	60	4.24	4.17	4.45	4.42	46	28	4.15	4.08	4.40	4.31	41.8
3	Good, but female young	43	41	4.12	3.84	4.53	4.40	12	9	3.56	3.80	3.85	3.85	20.0
		154	152	4.41	4.13	4.66	4.39	79	58	4.11	3.81	4.36	3.99	30.9

In table 5 the final averages, computed from individual not from grouped data, confirm the findings of Donaldson ('06), of Jackson ('13), and of King ('15), that in the rat the living male is heavier at birth than the living female. They show, also, that this same relation is found among the stillborn; the difference between the body weights of the two sexes averaging about 0.30 gram in each case.

In each of the three groups given in table 5, the living young, both males and females, have a heavier birth weight than the stillborn young, the final averages indicating a difference of 0.30 gram for each sex. Obviously the body-weight relations between the living and the stillborn young would be just the reverse of that shown above if the size of the individual is a determining cause of birth mortality. When the average body weights for

the largest of the living and the largest of the stillborn in each group are compared, the result shows conclusively that the size of the fetus is not a cause of death at birth, since in all three groups the average body weight of the largest living individual of both sexes exceeds that of the largest stillborn individual in the corresponding group. In this instance, also, the final averages show a difference of 0.30 gram in favor of the living young.

In man multiple births are the exception, not the rule as in the rat, so in this respect conditions in these two species are radically different. It is not so much the weight of the fetus as the size of the head that is responsible for the death of many infants, particularly boys. The deaths from this cause and those due to other forms of mechanical obstruction to birth comprise about 10 per cent of all human stillbirths, according to various observers.

The data given in table 5 show that the stillbirths formed 30.9 per cent of the total of 443 births in fifty-nine litters of albino rats. In collecting these data there was no error, since the litters were obtained at the time of birth and all of the young recorded. In the total of 253 litters containing stillborn young that were obtained during a period of five years, the birth mortality among 1817 individuals, as registered, was 22.8 per cent (table 1). The difference between these two sets of data would seem to indicate that at most 8 per cent of the stillbirths in the colony were not recorded. This error is not sufficiently large to invalidate any of the conclusions drawn from the records as they stand.

c. The physical condition of the mother as a cause of birth mortality

It requires but little experience in the handling of albino rats to determine from the general appearance of an animal whether or not it is in good physical condition. Alert animals of large size, having clear eyes and thick, glossy hair, are usually in excellent condition and free from disease. On the other hand, labored breathing, rough hair, dark red eyes, sluggish movements, and relatively light body weight are all evidences of poor physical condition and generally indicate that the animal is in an advanced stage of 'pneumonia.'

Table 6 shows the age, body weight, and general physical condition of the fifty-nine albino females that gave birth to the young whose body-weight data are given in table 5.

The first group in table 6 comprises twenty females that were apparently in good physical condition at the time of parturition, as was indicated not only by their general appearance and behavior, but also by the fact that they weighed, on the average, over 15 grams more than the 'standard' body weight for breeding females of the same age (Donaldson, '15). The average body weights of their young at birth exceeded those of the young cast by females in poor condition (cf. group 1 and group 2; table 5), thus adding more evidence that "rats in good physical

TABLE 6

Data regarding the age, body weight, and general physical condition of the fifty-nine female albino rats that cast the litters recorded in table 5

GROUP	GENERAL PHYSICAL CONDITION OF FEMALES	NUMBER OF FEMALES	AVERAGE AGE OF FEMALES AT PARTURITION	AVERAGE BODY WEIGHT OF FEMALES AT PARTURITION	STANDARD BODY WEIGHT FOR AVERAGE AGE OF FEMALES AT PARTURITION (DONALDSON, '15)
			days	*gms.*	*gms.*
1	Good	20	202	224.4	209.1
2	Poor	26	244	190.7	220.0
3	Good; but female very young	13	99	143.7	146.2

condition bear young with a birth weight considerably above that of the young cast by females in poor condition" (King, '15). Each female in this group gave birth to a litter that contained, on the average, two stillborn to six living young (table 5). Since these stillbirths cannot be ascribed either to mechanical obstruction to birth, to abnormal development, nor to infectious disease, it would appear that they must have been caused by some other prenatal condition that adversely affected the vitality of the young.

Examining the history of the mothers, as kept on record cards, it was found that five of the females in this group were nursing young at the time that the litter containing stillborn young was

cast; eight of the females gave birth to very large litters containing ten or more members; three females were over fifteen months of age at the time of parturition. No reason can be assigned for the presence of stillborn young among the offspring of the remaining four females in this group. It is possible, perhaps, that these females were in early stages of 'pneumonia' which had not as yet altered either their general appearance or their body weight, but had already affected their body metabolism in such a way as to adversely influence the development of the fetal young.

The second group in table 6 comprises twenty-six females that were obviously in bad physical condition at the time that their litters were cast. These females were, on the average, some 30 grams under the 'standard' body weight for breeding females of the same age, and the birth weights of their young were very low (table 5). It is of interest to note that the percentage of stillbirths in the total number of young cast by these females was relatively very high (cf. group 1 and group 2; table 5). The majority of the females in this group were obviously suffering from 'pneumonia;' three of them were in such an advanced stage of the disease that they had to be killed as soon as the litter was cast.

d. The age of the mother as a factor in birth mortality

It has already been shown that litter size in the albino rat is influenced to a considerable extent by the age of the mother (Slonaker, '12; King, '16 a), and it is possible that the viability of the young at birth may also be affected by this same factor.

As already noted, three of the females in the first group of table 6 were over fifteen months of age when casting a litter that contained stillborn young. These females appeared to be in good physical condition, yet their litters were very small, and seven of the eleven young cast were dead at birth. The third group of table 6 comprised thirteen females that had an average age of only ninety-nine days when casting their first litter. Although each of these females was seemingly in good health, twenty-one in the total of 105 young were stillborn (table 5).

Since none of the females in these two groups showed any evidence of disease at the time of parturition, it is probable that the age of the mother, and not incipient 'pneumonia,' was the chief factor responsible for the high birth mortality in their young. The age of eighteen months marks approximately the end of the reproductive activity of the albino female, and toward its close, as at its beginning, there seems to be a strong tendency for the females to cast fewer individuals in a litter and a relatively greater proportion of stillborn young. This phase of the subject will be discussed later.

In considering the causes responsible for stillbirths among human offspring, the age of the mother is a factor that is usually ignored or assigned a very minor rôle. Various series of reliable statistics, however, indicate that the birth mortality is relatively high in children of very young and of very old mothers, so evidently the age factor has greater influence in this respect than is generally assumed. The trend of statistical evidence on this point is shown by the following examples. Whipple's ('19) analysis of the birth statistics for the city of Boston during the period from 1891 to 1910 shows that: "The percentage of stillbirths arranged according to the age of the mother gave the very high percentage of 11.1 per cent for mothers under 20 years of age, 4 per cent for age group 20–24, 5.1 for 25–29 years, 4.4 for 30–39 years, and 3.3 for ages over 40."

Far more comprehensive data regarding the effect of the age of the mother on birth mortality among the young are given by Davis ('20) in his study of the births in the registration area of the United States during the year 1918. In a total of 1,372,329 births in which the age of the mother was ascertained, there were 46,122 stillbirths. The percentage of stillbirths was 3.9 for mothers under twenty years of age, 3.2 per cent for mothers from twenty to thirty-nine years, and 5.4 per cent for mothers over forty. This study indicates that the percentage of stillbirths is much higher in children born to mothers at the beginning and at the end of the reproductive period, and its findings are confirmed by the birth statistics gathered by The Children's Bureau (Duke, '15; Duncan and Duke, '17; Allen, '19; Dempsey, '19),

which have already been given in table 3 of the present paper. They are shown again in table 7, arranged according to the age of the mother at the time that the birth of her child occurred. It will be noted that table 3 gives a total of 5,456 births, while table 7 registers only 5,452 births. This discrepancy is due to the fact that in four cases the age of the mother was not ascertained.

Nearly 90 per cent of the births registered in table 7 were those to women between twenty and thirty-nine years of age, the remaining 10 per cent were evenly divided between women that were under twenty and over forty. As this is about the normal distribution of births relative to the age of the mothers, a comparison of the percentages of stillbirths as given seems permissible.

TABLE 7

Data for human births, collected by the U. S. Children's Bureau (table 3), arranged according to the age of the mother at the time of parturition

MOTHER'S AGE IN YEARS	TOTAL NUMBER OF BIRTHS	LIVING BIRTHS	STILLBIRTHS	PER CENT STILLBIRTHS IN TOTAL NUMBER OF BIRTHS
Under 20	282	263	19	6.95
20 to 39	4,882	4,683	199	4.07
40 and over	288	268	20	6.94
	5,452	5,214	238	4.36

Table 7 shows clearly that in this set of records, as in those given by Whipple and by Davis, the percentage of stillbirths is correlated with the age of the mother. In table 7 the stillbirths formed only 4.07 per cent of all births to women at the zenith of the child-bearing period, while they were increased to nearly 7 per cent in the births to women at the extremes of the reproductive period.

When the data in table 7 are arranged according to the order of the birth, as is shown in each of the papers in which the separate sets of data are given, it is found that the percentage of stillbirths is higher for the first births and for those after the sixth than for the intermediate births. A series of birth statistics arranged in this manner is, of necessity, an age series, and it is

more probable that the observed variations in the percentage of stillbirths depend on the age factor rather than on the number of the pregnancy.

It has been claimed that the high birth mortality in children of very young mothers is due chiefly to the mother's ignorance of the proper hygienic laws that should be observed by pregnant women. This explanation cannot be offered to account for the increase in the percentage of stillbirths among the children of women over forty, however, since births at this age are rarely those of the first pregnancy. It seems probable that both at the beginning and at the end of the reproductive period physiological conditions incident to age are responsible in great part for the high birth mortality among the children born at this time.

c. Congenital debility as a cause of birth mortality

Stillbirths among human offspring not traceable to a well-defined cause are generally ascribed to 'congenital debility,' this term being used to indicate a lack of sufficient vitality in the fetus to render postnatal existence possible. Various series of investigations show that a very considerable proportion of stillbirths are attributed to this cause. For example, in 201 cases of stillbirths at term studied by Brothers ('96), over 50 per cent were classed as due to 'congenital debility,' while Waldvogel's ('13) studies led to a similar conclusion.

In the sense in which the term 'congenital debility' is used above, practically all stillbirths in the rat might properly be grouped under this heading, since in all cases so far found impaired vitality of the fetal young was seemingly the direct cause of the birth mortality; the underlying cause is discussed in the following section.

GENERAL DISCUSSION

This study has shown that in two important respects the statistics for the birth mortality in the albino rat accord in a most striking manner with those for man: 1) the sex ratio in the living young at birth is practically the same in both forms (about 105.5

males to 100 females); 2) the great excess of males among human stillborn finds its parallel in the high sex ratio which characterizes the stillborn of the rat (129 males to 100 females). In one respect only the birth records for these two forms do not agree. The normal percentage of stillbirths in human offspring (4 to 5 per cent) is at least twice that in the albino rat (table 2). This difference, however, is readily explicable. Factors which are responsible for about one-half of all human stillbirths, i.e., mechanical obstruction to birth, accidents, faulty implantation, and infectious disease, ordinarily play little, if any, part in the birth mortality in the rat. If stillbirths due to these causes are eliminated, the birth mortality among human offspring falls to about 2 per cent, which is close to the percentage of stillbirths which is seemingly normal for the albino rat when large numbers of breeding animals are kept under fairly uniform conditions of environment and of nutrition. The stillbirths in man which thus seem comparable to those in the rat, are those that, in general, are attributed to 'congenital debility,' this term, as already stated, being used to indicate that the fetus possesses such a low state of vitality at the end of term that it is incapable of independent existence. From the evidence at hand the great proportion of stillbirths in the rat can be attributed to the same cause.

The question at once arises as to the cause of this impaired vitality in the fetus and whether it is possible to control it so that the percentage of stillbirths will be materially decreased. If we consider those cases in the albino rat in which the stillborn young were obtained at the time of birth and the age and physical condition of the mothers noted (tables 5 and 6), it is found that the great majority of them occurred in litters of females that were suffering from disease, chiefly 'pneumonia,' or in those of females at the extremes of the reproductive period, while in a few cases the litters were very large or were cast by females that were suckling young at the time of parturition. Extensive series of breeding experiments extending over a period of a dozen years and covering the birth of many thousands of rats lead me to believe that practically all stillbirths in this animal occur under

one or another of these conditions. The one factor which seemingly might have affected the vitality of the fetal young in all of these cases is malnutrition.

The nutrition of the fetal young is a very complex process, and in its broadest sense it includes the absorption and the assimilation of food by the mother as well as its transmission through the placenta to the young. Any factor or physiological condition that adversely affects the normal metabolic processes upon which any phase of embryonic nutrition depends therefore indirectly influences the development of the young and may impair their vitality to a greater or less extent.

Let us consider in some detail the effect of the various factors that are apparently responsible for stillbirths in the rat. The rat scourge, 'pneumonia,' is a wasting disease, and as such profoundly affects all of the normal life processes in an animal affected with it. The living young cast by females having this disease in an advanced stage are usually very small and emaciated at birth, and their vitality is at such a low state that they are difficult to rear even when suckled by a vigorous foster-mother. There can be no question but that the fetal young suffer throughout the entire course of their intra-uterine existence from malnutrition, since the illness of the mother must interfere with her power to assimilate food and to transmit it to her offspring. With such a handicap to their normal development, it is not surprising that a large proportion of the young are not able to survive at birth.

The suckling of young, particularly if the litter is above the norm (seven) in size, is as a rule a severe strain on the nutritive reserve of the mother, as is shown by the fact that she usually loses considerable weight during this period unless she is in excellent health and abundantly supplied with food. Not infrequently a lactating female is also carrying a second litter. If one or both of these litters are large, the amount of food that the mother can assimilate and supply to her young, in addition to her own needs, is inadequate for the proper nutrition of all of the individuals concerned. The result is that the suckling young usually grow very slowly and show every evidence of being un-

derfed, and the gestation period of the fetal young is lengthened from one to several days, owing doubtless to the fact that the implantation of the fertilized ova is delayed (King, '13; Kirkham, '16). Here again malnutrition is obviously a factor that impairs the vitality of the fetal young and tends to increase the proportion of stillbirths. A similar explanation can be offered for the presence of stillborn young in litters of exceptionally large size. In these cases the inadequate nutrition of the young is indicated by the fact that all members of the litter are, as a rule, of small size and under normal weight at birth.

The fact that the proportion of stillborn young in litters cast by very young and by very old females is markedly greater than that in litters cast by females at the height of their reproductive activity indicates that the age of the mother is a factor of importance in birth mortality. Donaldson ('06) has shown that one year of a rat's life is equivalent to thirty years of human life. At the age of eighteen months, therefore, a female rat corresponds physiologically to a woman of forty-five years, and it can hardly be a coincidence that this age marks approximately the end of the reproductive activity in both species. The onset of puberty does not, however, correspond as closely in the two forms, since rats breed at three months of age. Age has a profound effect on all of the normal activities of the body, and it is not surprising, therefore, to find that the immaturity of the young mother and the physiological changes in the uterus incident to the approaching menopause seemingly inhibit the metabolic processes concerned with the nutrition of the fetal young. In such cases the young often suffer from impaired nutrition, and consequently the birth mortality among them is much greater than that among the offspring of females at the height of their reproductive activity.

It has been repeatedly demonstrated that a mature, well-developed albino female that is in good physical condition at the time of conception, will, if abundantly supplied with proper food during the entire gestation period, cast a litter containing only living, vigorous young that have relatively heavy birth weights. A special experiment recently made to test this point has given

rather astonishing results. The young cast by a mature female abundantly supplied with rich food during the gestation and lactating period were twice the normal weight at birth, and at thirty days of age, when weaned, they were over 200 per cent above the average weight of rat at this age. At sixty days of age the males in this litter had an average body weight of 260 grams, which is some 300 per cent above the 'standard' weight for males of this age. On the other hand, inadequate feeding of breeding females invariably leads to the production of small litters containing undersized individuals in which there is a high percentage of stillbirths. This fact was fully demonstrated in the early stages of an inbreeding experiment with these animals which has been carried on for some years in our colony (King, '18). Even when the food supply is ample, the present study has shown that in lactating females, in those carrying a very large litter, and in those suffering from disease or breeding at one extreme of the reproductive period, physiological conditions within the body of the mother may adversely influence the various processes upon which the nutrition of the young depends and thus lead in many cases to the death of a considerable proportion of the young at birth.

Conditions of human existence are so complex and so artificial in many cases that one would hardly venture to assert that the underlying cause of all cases of 'congenital debility' was malnutrition of the fetus due to the age or to some abnormal physical condition of the mother, yet the evidence at hand is strongly in favor of such a view. Inadequate nutrition of the young is certainly a potent factor in the birth mortality of the rat, and it probably plays an important rôle in the birth mortality of other mammals, including man. The maintenance of pregnant females under environmental and nutritive conditions favorable to the health of the mother and to the adequate nourishment of the fetal young throughout the entire gestation period, not merely near its close, would, therefore, undoubtedly lead to the birth of more vigorous young and to a marked decrease in the number of abortions and of stillbirths.

Whenever large groups of human birth statistics have been analyzed it has been found that the mortality among the males is very high, the sex ratio for the stillborn being at least 25 points higher than that in the living young. This same phenomenon appears also when a large series of birth data for the rat are examined (table 1), and it likewise is present in statistics for the horse, if Goehlert's ('82) records are reliable. Since the disparity between the sex ratios for the stillborn and those for the living young in these various groups of statistics is fairly constant and much too great to be considered as within the range of normal variation in the sex ratio, there must be some fundamental cause, founded on a difference in the constitution of the male and female organisms, that is responsible for the excessive mortality among the males at birth.

Düsing ('84) discusses this subject at considerable length, and he concludes that: "Die Knaben sterben also während Fötallebens häufiger als die Mädchen, weil viele derselben sich unter ungünstigen Ernährungsverhältnissen ausbilden, während sie, da sie durchschnittlich schwerer sind, sogar mehr Nahrung beanspruchen als die leichteren Mädchen." Since from the time that the sexes can be distinguished at about the sixth week of pregnancy the excess of males among aborted embryos is greater the earlier the age at which abortion occurs (Rauber, '00; Nichols '07; Auerbach, '12; Carvallo, '12), inadequate nutrition cannot well be considered as the primary cause of the greater mortality among male fetuses in general.

A most suggestive hypothesis that may have a very important bearing on this problem has recently been advanced by Lillie ('17) in his study of the action of sex hormones in producing the 'free-martin' in cattle: "It seems probable that the disturbance of the equilibrium that protects the male from the sex hormones of the mother would result in malformations of the male sex characters to a degree commensurate with the extent of the disturbance. There is, therefore, here a possible explanation for the greater mortality among male foetuses." Our knowledge of the action of sex hormones is as yet too meager to enable us to

advance a definite theory regarding the influence of these factors on fetal mortality.

Nichols ('07) states that three explanations are open to consideration to account for the heavy mortality among boys at birth "(a) the initial numerical preponderance of males; (b) the greater proportion of deaths of male fetuses occurring during parturition owing to their larger size; and (c) the intrinsically much greater mortality of males than of females in the earlier period of life, both antenatal and postnatal." Nichols assigns only a minor rôle to the first two of the causes enumerated above, and he concludes that:

> Obviously the main cause of the great preponderance of male stillbirths resolves itself into the question of the comparative mortality or death rate of the male and female sexes during the intrauterine period of existence. . . . . it is therefore obvious that the male constitution is intrinsically weaker, less hardy, and more susceptible to morbific and mortific influences, and has less vitality and resisting power against disease, than the female. The cause of this innate disparity of vitality between the two sexes we do not know; but the fact that it exists, that the antenatal mortality and death rate of males much exceeds that of female fetuses, accounts for the great excess of male over female stillbirths.

In the light of the recent researches in heredity it is conceivable that the inherent dissimilarity between the sexes as regards their constitutional vigor, which has been discussed in detail by Geddes and Thomson ('01), may have its basis in the germinal structure of the fertilized egg. From the work of Guyer (10) and of von Winiwarter ('12) on the spermatogenesis of man, and of Allen ('18) on the spermatogenesis of the rat, it is known that in both of these mammals the spermatozoa are dimorphic, one kind of spermatozoa having one more chromosome than the other; both kinds of spermatozoa are produced in equal numbers and both kinds, as far as known, are equally functional. The current theory of sex determination postulates that the spermatozoa containing the extra, or X-chromosome, are 'female-producing'; those lacking it are 'male-producing.' The fertilized ovum that is to develop into a female thus contains two X-chromosomes, while that having only the X-chromosome received from the mother

develops into a male. May not the difference in the constitutional vigor of the two sexes depend, in some way, upon the fact that the chromatin content of the female ovum is greater than than of the male ovum? One might suggest, perhaps, that the excess of chromatin brought into the egg by the 'female-producing' spermatozoan influences the ensuing interaction of the chromatin and the cytoplasm in such a way that the embryo becomes endowed with a constitution that is more stable and more vigorous than that of the embryo developing from an egg in which the initial amount of chromatin is less. Such an hypothesis is, of course, only tentative. Until our knowledge of heredity and of the sex-determining mechanism is greatly increased it will be futile to theorize as to the probable cause for particular characters associated with one sex or the other which seemingly do not depend upon the action of specific genes.

The great excess of males among aborted and stillborn fetuses is readily explained if we assume that, from the time of conception, the embryo that is to develop into a male has a constitution inherently weaker than that of the embryo that is to become a female. During the gestation period many factors, such as disease, unfavorable environmental conditions, physiological changes incident to age, etc., may lessen the mother's power of assimilating food and of transmitting it to her fetal young. Under these conditions, a male fetus possessing a relatively low initial vitality would be more severely handicapped by inadequate nutrition or by conditions unfavorable to normal development than would a female fetus having a greater initial vigor of constitution and more power to resist unfavorable environmental conditions. One, therefore, would expect to find the facts exactly as shown by various series of investigations cited in this paper, namely, that at all stages of gestation and at birth the mortality among the males is far greater than that among the females.

SUMMARY

1. Birth statistics collected during a period of five years show that in a total of 31,670 newborn albino rats 415, or 1.3 per cent, were stillborn. Allowing for the probable error in recording the

data, it would appear that under normal environmental conditions not more than 2 per cent of rat fetuses are dead at birth.

The most accurate statistics available indicate that the normal birth mortality in man is about 4 per cent. There are no data of value regarding the percentage of stillbirths in other mammals.

2. The normal sex ratio in newborn albino rats, including the stillborn, is about 107 males to 100 females; in man the sex ratio for the living young at birth averages about 105.5 males to 100 females, and if the stillborn are added the sex ratio rises to about 108 males to 100 females.

3. In each year that the mortality records for newborn rats were taken there was a pronounced excess of males among the stillborn, the sex ratio in the total number of such individuals being 129.3 males to 100 females (table 1).

Large series of birth statistics collected in many different countries show that the sex ratio among stillborn children is very high, averaging about 130 to 140 boys to 100 girls. The excess of boys becomes greater the earlier the month of pregnancy in which the fetus dies.

4. In the rat the percentage of stillbirths seems to vary somewhat with the seasons, being least in the spring and greatest in the autumn months when the breeding animals are suffering from the devitalizing effects of high temperature during the preceding summer (table 4). The birth mortality among human offspring does not, apparently, vary to any appreciable extent at different periods of the year.

5. Data collected during one year show that the mortality among young rats during the first three days after birth was 2.3 per cent, or slightly greater than the birth mortality in the colony during the same period (2.16 per cent); infant mortality in man during the first month after birth is about 5 per cent, or 1 per cent higher than the birth mortality.

Postnatal mortality in the rat is largely due to accidental causes which tend to kill more females than males; in man the death of many infants is traceable to prenatal causes which seemingly are more fatal to boys than to girls.

6. Factors responsible for a considerable proportion of the stillbirths among human offspring, such as, infectious disease, faulty implantation, mechanical obstructions to birth, including the size of the fetus, apparently play no part, ordinarily, in the birth mortality of the rat.

7. From the data obtained it appears that malnutrition is directly responsible for most of the stillbirths in the rat. Factors influencing the food supply of the fetal young, such as the physical condition and the age of the mother, the suckling of young, and the size of the litter carried, are therefore the chief causes of birth mortality in the rat.

8. Available evidence indicates that both in the rat and in man the male fetus is intrinsically weaker than the female, and therefore more susceptible to prenatal influences inimical to normal development. A tentative hypothesis is advanced that the difference in the constitutional vigor of the sexes has its basis in the different chromatin structure of the male and female zygote.

Resumen por el autor, David M. Siperstein.
Universidad de Minnesota.

Los efectos de la inanición aguda y crónica sobre el desarrollo y la estructura del testículo de la rata albina.

El desarrollo postnatal normal del testículo ha sido estudiado por el autor en una serie de ratas albinas. Estos testículos fueron comparados con los de ratas sometidas a una alimentación deficiente durante varios periodos. Unas cuántas ratas fueron alimentadas con una dieta abundante después de una inanición prolongada. Los resultados más importantes de estos estudios son los siguíentes: I. En ratas de dos dias el testículo aumenta en peso a pesar de haber sometido al animal al hambre durante 48 a 50 horas, pero las mitosis disminuyen en número y el proceso normal de la diferenciación histológica cesa. 2. Durante el periodo de nutrición deficiente durante tiempo variable en ratas de tres semanas, la mitosis continúa en las células de los tubos seminíferos, pero el proceso de la espermatogénesis cesa en el estado de espermatocito primario. Los espermatocitos degeneran y son reabsorbidos. Las espermatogonias y células de Sertoli solamente presentan cambios degenerativos en los casos de inanición extrema. 3. La inanición aguda en las ratas adultas con pérdida del 30 a 47 por ciento del peso total produce cambios degenerativos en unos cuántos túbulos esparcidos irregularmente. Todos los demás túbulos presentan una estructura normal en apariencia. 4. La mitosis es muy persistente en el epitelio seminífero y tiene lugar aún en aquellos túbulos en los cuales casi todas las células aparecen más o menos degeneradas. 5. La alimentación abundante después de una inanición prolongada (comenzada a las tres semanas de edad y extendida sobre 12 a 20 semanas) da como resultado la vuelta rápida a la estructura histológica normal. 6. Durante el periodo regenerativo el autor ha comprobado la existencia de una hipertrofia definida del tejido intersticial e hiperplasia de las células intersticiales.

THE EFFECTS OF ACUTE AND CHRONIC INANITION UPON THE DEVELOPMENT AND STRUCTURE OF THE TESTIS IN THE ALBINO RAT

DAVID M. SIPERSTEIN

Institute of Anatomy, University of Minnesota, Minneapolis

FOURTEEN FIGURES

CONTENTS

The immediate and the remote effects of inanition upon the young organism are subjects of interest and importance, especially at the present time. Experimental studies in this field have yielded much of importance to biology in general and to medicine in particular. It is very desirable to know more about the changes produced in the sex glands of malnourished or undernourished infants and children, and the resulting effects upon the reproductive system in later adult life. Inanition in adults may also occur either alone or associated with acute or especially with chronic wasting diseases, causing degenerative processes

in the sex glands. Recent work on vitamine deficiencies (by McCarrison, Allen, Dutcher, and others) indicates that the changes produced in the sex glands by this partial inanition resemble those found after general inanition. A study of the changes occurring in the histological structure of the testis of the albino rat during experimental inanition at various ages was therefore undertaken, and the results are embodied in the present paper.

MATERIAL AND METHODS

A large part of the material for this investigation was presented to me by Dr. C. M. Jackson, to whom the writer is also very much indebted for constant advice, aid, and criticism throughout the course of this study. The material comprises the testes of several albino rats (Mus norvegicus albinus) that had been subjected to inanition experiments in the Institute of Anatomy. The adult animals during acute inanition were allowed water only; but one of the adults was placed on total inanition, as were also the young rats (two days old) which were removed from the mother and given neither food nor water. Those on chronic inanition were fed restricted amounts of Graham bread soaked in whole milk for various periods. Some were refed fully after underfeeding for various periods. The animals were killed by chloroform and autopsied, the testes being weighed (without epididymis) and portions fixed for histological study. For convenience the material at my disposal is grouped as shown in table 1. In the first column, representing the individual rat numbers, the letters indicate the series (those autopsied by myself are 'Si'), the number following indicates the litter, while the number after the decimal point identifies the individual rat.

The testes had been fixed in either Zenker's, Bouin's, or Flemming's fixatives. Paraffin sections were cut at 2 to 10μ in thickness. The sections were stained chiefly with haematoxylin and eosin. Weigert's iron haematoxylin counterstained with Van Gieson's stain, or Heidenhain's iron-alum haematoxylin counterstained in some instances with orange G or acid

fuchsin. In general, Heidenhain's iron-alum haematoxylin without any counterstain gave by far the best results.

My own material was fixed in Carnoy's mixture (no. 1) and in Bouin's fluid. Fixation for one hour with Carnoy's mixture was found to be best. Sections were stained with Heidenhain's iron-alum haematoxylin with or without counterstain (acid fuchsin). This gave clear-cut karyokinetic figures in all stages of mitosis.

A number of measurements of cross-sections of tubules were also taken from the stained sections by means of a micrometer eyepiece. Sections of each testis containing the largest number of tubules cut in cross-section were chosen. In each section all the tubules showing a true cross-section (approximately circular) were measured. The results embodied in table 1 are therefore the average of measurements of a variable number of tubules, ranging from 8 to 44 in the individual cases. While the observations are relatively few in number, they are sufficient to indicate clearly any marked change in size.

In addition, a few (ten to fifteen) nuclei of the interstitial cells in both the control and the test rats were measured at various stages and the averages calculated. Only a sufficient number of testes was taken from each group to determine whether any marked change in the size of the nuclei had taken place as a result of the test conditions. The results are listed in table 1. No measurements of the cell body were attempted, on account of the irregularity of form. Measurements on the seminiferous epithelial cells were likewise found to be impracticable.

OBSERVATIONS

1. Normal postnatal histogenesis (group 1)

In order to understand more fully the changes which inanition produces in the testis, it is essential to review briefly its normal histological structure and histogenesis as a basis for comparison.

Newborn (fig. 1). In microscopic sections of the testis in the newborn rat, the seminiferous tubules appear closely packed together at the periphery of the testis, while in the center of the

section the tubules are less compactly arranged. The tubules average 37.2μ in diameter. The intertubular spaces contain many small capillary vessels and mesenchymal cells. The tubules themselves consist chiefly of a single layer of parietal epithelial cells, which apparently correspond to those designated as 'Sertoli cells' by v. Ebner ('02) in the testis of the colt. These cells fuse to form a syncytium. Lumina have not yet appeared in the tubules. The central portion of each tubule contains from one to three large clear cells, each containing a definite, well-marked nucleus. Each nucleus has from one to three small clumps of chromatin situated usually (but not always) close to the periphery of the nucleus. These masses probably represent chromatin nucleoli. These large central cells apparently correspond to those described by v. Ebner ('02, fig. 1147) as the primitive germ cells ('Ursamenzellen') from which the spermatogonia are probably derived.

Interstitial cells (of typical structure) have not yet developed. There is present, however, in the intertubular tissue a peculiar type of cell which appears to be the forerunner of the later interstitial cells (fig. 14, *A*). This cell contains a large round nucleus (average diameter, 7.1μ) extremely rich in chromatin, which in turn is surrounded by a narrow rim of clear cytoplasm. By the form of its nucleus and its deeply staining chromatin, it is easily distinguished from the ordinary young mesenchymal or connective-tissue cell.

Fourth day (fig. 2). In a normal rat at four days of age the development of the testis has advanced considerably. The whole section is filled with seminiferous tubules (average diameter, 41.7μ). Within the tubules themselves the parietal cells show no material increase in number, but the spermatogonia (Allen's cell type A) have appeared. They are probably derived from the central cells ('Ursamenzellen' of v. Ebner), which still occur (less numerously) and present mitoses, though less frequently than in the newborn. Before dividing, they often appear to migrate from the center of the tubule toward its periphery and crowd in among the parietal cells. Some tubules already contain a few cells which resemble Allen's type B; that is, a

primary spermatocyte cell in its earliest phase. The forerunners of the interstitial cells are beginning to group themselves together in the intertubular spaces.

One week (fig. 3). A section of the testis from an albino rat at seven days shows an increase in the number and size of the tubules (average diameter, 50.5μ). (The larger number of tubules appearing in a cross-section of the testis may, however, be due to an increase in the length of the tubules rather than an actual increase in their number.) This represents the earliest stage described by Allen ('18). The tubules now contain two or three layers of cells. Very few central cells still remain, but spermatogonia (Allen's type A) are present in large numbers. There are very few type B cells. In other words, an undifferentiated condition of the spermatic epithelium still prevails. The syncytium (Sertoli syncytium) which fills the tubules at this stage is exceptionally well shown. The number of mitotic figures has again increased, so there are now as many figures in the field as there were at birth. The interstitial cells are more numerous and the amount of interstitial tissue is increased.

Two weeks (fig. 4). There is a large increase in the apparent number of seminiferous tubules, and their average diameter has increased to 65.3μ. There are many cells of types A and B, and some tubules even show Allen's type C (spermatocytes in which the chromatin masses become more diffuse than in type B and assume a 'woolly appearance'). A few cells have advanced as far as the leptotene stage. It is now fairly easy to distinguish between Sertoli cells and spermatogonia. The Sertoli cell has a nucleus with only a little chromatin material, in this way differing from the nucleus of the spermatogonium, which has a large amount of deeply staining chromatin.

Three weeks (fig. 5). Lumina are just beginning to appear in the closely packed tubules, whose average diameter has now increased to 99.7μ. Spermatogonia, cells of types A, B, and C, are numerous. A few tubules already contain primary spermatocytes showing mitotic figures. In many places, degenerating primary spermatocytes and spermatogonia are also present. This appears to be a normal physiological process, occurring in

the testis at all ages. No secondary spermatocytes or spermatids are to be seen. The interstitial tissue is assuming its adult structure (fig. 14, *B*). The nuclei average only 4.7μ in diameter, which is much smaller than at birth (7.1μ).

One month (fig. 6). The testis at this stage shows only a slight advance in development. It is distinguished by the large number of primary spermatocytes present. Spermatids have not yet appeared. The interstitial tissue shows no change.

Six to ten weeks. Sections of testes from forty-three to seventy days of age show a gradual increase in the size of the tubules (table 1) and in the number of mature sperm elements. Mature spermatozoa appear for the first time at the age of forty-three days. Their number increases so rapidly that at eight weeks (fig. 7) the histological structure of the testis differs in no important respect from that in the older rats. The interstitial cells show no noticeable change in structure.

Judging from the statements of Hewer ('14) and Allen ('18), there appears to be considerable variation in the age at which the various steps in the process of spermatogenesis occur in the albino rat. Hewer reported that there is no differentiation of primary spermatocytes from spermatogonia until the twenty-fifth day after birth. Allen found that his rats reached the pachytene stage at two weeks; while my material first shows this stage at three weeks. Hewer found that lumina first appear in the tubules at seven weeks. Allen demonstrated them in all rats fourteen days old. In my own rats fourteen days old I found no evidence of definite lumina, but they begin to appear at twenty-one days. Hewer stated that spermatozoa are not present in the lumina of the tubules until nine weeks after birth. Allen found spermatozoa in rats at the age of thirty-seven days, which corresponds closely with my observation at forty-three days.

2. Changes in young rats subjected to acute inanition (Group II)

A comparison of the testes of the normal control (at four days) with those of the test animals of same age (but lesser body weight) in table 1 shows but little apparent retardation in the growth

in weight of the gonads of the latter (average weight in two controls, 0.0053 gram; in three test rats, 0.0046 gram). Although the test rats were kept on total inanition for forty-eight to fifty hours, the testes have evidently maintained nearly normal growth, although the body weight has decreased 21 to 25 per cent.

The remarkably persistent growth of the testes in the starved rats is especially evident upon comparison with the newborn of the same litter (Si 1.4). The starved rats have decreased in body weight until they, although four days old, are about 20 per cent below the normal newborn. The testes, however, show a large increase in weight (in spite of the total inanition). The change in weight from 0.0029 to an average of 0.0046 grams represents an increase of 59 per cent. This is in general agreement with the results of Stewart ('18), who found that in rats kept at maintenance (constant body weight) by underfeeding from birth to (average) sixteen days the testis apparently increased about 374 per cent in weight. The smaller increase in the testes of my starved rats is probably due to the greater severity and shorter duration of the inanition.

My measurements indicate that this increase of 59 per cent in the weight of the testes is due almost entirely to the increased number of tubules seen in a section. The size of the tubules has remained about the same. There has perhaps been some retardation of the normal growth in size of the tubules. The normal testis at four days shows an average tubular diameter of 41.7μ, while the average diameter of the tubules in group II is only 38.4μ. This small difference, however, is of doubtful significance.

All three of the starved young rats (Si 1.1, Si 2.3, Si 2.6) show practically the same histological structure in the testis. The tubules are close together and more numerous than in the newborn, although there are relatively few in the center of the section. Cell differentiation has not progressed much beyond that found in the newborn. Each tubule presents the single layer of parietal cells. These cells are all alike and contain large nuclei, with very little chromatin material, surrounded by a

narrow strip of clear cytoplasm. The central cells ('Ursamenzellen' of v. Ebner) like those already described in the normal testis are also still present. There are very few mitotic figures either among the parietal cells or the central cells (fig. 8). Sections (stained with iron-alum haematoxylin) of the testes of controls show many mitotic figures in each field (figs. 1 and 2). This decrease in the number of karyokinetic figures is probably due to the condition of inanition. In general, the histological picture shows that the testis has advanced to the stage when type A cells are beginning to appear. Thus the stage of differentiation is somewhat beyond that corresponding to the normal at similar body weight, but behind that corresponding to the age or actual testis weight. The increase in the (apparent) number of tubules evidently accounts for the increase in the size (weight) of the testis.

Swingle ('18) similarly found that total starvation inhibits the growth and metamorphosis of Rana pipiens larvae. Spermatogenesis ceases and sex differentiation is prevented.

3. Changes in rats held at maintenance by underfeeding from three to ten weeks of age (group III)

In the five rats of this group held nearly at constant body weight by underfeeding from three to about ten weeks of age, the testes, though below normal weight for that age, have been retarded in their growth far less than has the body weight. Thus on comparing the average data for group III (table 1) with the normal control at three weeks (Si 6.0) it appears that the body weight has increased from 20.6 grams to 26.9 grams, an increase of about 31 per cent; while the testes have increased from 0.0920 gram to an average of 0.1955 gram, an increase of about 113 per cent. This would indicate a relative growth for the testis even greater than that (+34 per cent) found by Jackson ('15 a) under similar conditions. Individual variations in the control or test rats probably account for the difference.

The size of the tubules in group III has apparently increased from an average diameter of 99.7μ (normal at three weeks of

age) to an average diameter of 110μ. This increase in diameter (though of doubtful significance) would indicate that the increase in the weight of the testes is due in part to the increase in the diameter of the tubules.

With the exception of one rat (S 11.65), which will be mentioned later, the testes in this group all present the same microscopic picture (fig. 9). The tubules are placed close together. Lumina are just beginning to appear, although most of the tubules still show no central lumen. No spermatozoa or spermatids are present. There is no evidence to indicate that they had ever been developed and had undergone necrosis. A few secondary spermatocytes can be seen, but they are abnormal in structure.

Almost every primary spermatocyte also shows some degenerative changes. The cytoplasm becomes coarsely granular and contains clumps of basophilic staining material. Other cells show a fatty (?) degeneration or vacuolization of the cytoplasm (a positive statement cannot be made, as material stained for fat was not available). The nuclei degenerating by a process of karyorrhexis may give rise to the basophilic granules present in the cytoplasm of so many spermatocytes. The pycnotic nuclei are very abundant and, with progressive necrobiosis, appear gradually to lose their staining capacity, terminating in karyolysis. The cytoplasm also progressively loses its staining capacity and gradually disappears.

The spermatogonia, however, appear nearly normal. The Sertoli cells are increased in number, but show no structural changes. The tubules are filled with a structure resembling the 'degeneration reticulum' described by Kuntz ('20) in the testis after division of the nerves. This appears to me to be due largely to the Sertoli syncytium which becomes visible in direct ratio to the number of other cells which are being destroyed. Allen ('19) pointed out that in normal tubules the Sertoli syncytium is hard to see on account of the closely packed germ cells. As a result of experimental conditions, the syncytium is made more prominent by the removal of the germ cells which normally obscure it.

There are present in all cases many multinucleated or giant-cells. These cells are situated in the center of the lumen, and each tubule usually presents one or two of them. Each cell may contain from two to four nuclei, all showing some degenerative changes. Multinucleated cells appear to be very characteristic of the degenerative process in the testis. To a certain extent, the degree of severity of the starvation can be measured by the size of these cells and the number of nuclei they contain. For example, absolute inanition for nine days (in the adult) produces giant-cells containing as high as twelve to fifteen nuclei, while in the slower chronic inanition in the present group, the number is reduced to three or four nuclei.

One other important fact, which is strikingly illustrated in these sections, is the remarkable persistence of mitotic figures in the spermatogonia and primary spermatocytes. In rats which have been kept at constant body weight by underfeeding for seven weeks, the number and structure of the mitotic figures is apparently normal as compared with control rats (from three to four weeks). This fact is in agreement with the observations by many investigators (mentioned later) who have reported the presence of mitotic figures after prolonged chronic inanition. This mitosis is doubtless correlated with the persistent growth of the testis in the underfed young rats under these conditions, the new cells formed being in excess of those destroyed by degeneration.

My study of this group of albino rats kept at maintenance by underfeeding from three to ten weeks leads to the following conclusions: First, the chronic inanition prevents the testis from reaching the stage of spermatogenesis normal for the corresponding age. Second, in spite of the persistent mitosis and increased size of the testis, the process of spermatogenesis remains at the stage where spermatocytes are produced, corresponding to the normal stage at the age of three or four weeks. The growth capacity of the testis under these conditions of subnormal nutrition is apparently sufficient only to produce primary spermatocytes from the spermatogonia. Third, the spermatocytes degenerate and are absorbed, though not so rapidly as they are formed.

The excess of production over destruction partly accounts for the continued growth in weight of the testis. Fourth, the interstitial tissue is apparently unchanged and resembles in quantity and structure the tissue present in a normal rat at the age of three or four weeks.

In one rat (S 11.65, fig. 10) in this group, the testis shows such remarkable changes that it seems advisable to describe it separately. This was the left testis (indicated by (L) in table 1), which was markedly atrophic, weighing only 0.0496 gram. All the tubules show degenerative processes. Many contain no cells whatever. The lumina are filled with the characteristic 'degeneration reticulum,' and some have large vacuoles in their centers. Pycnosis, karyorrhexis, and karyolysis are prevalent.

A few of the seminiferous tubules in this case show a type of degeneration which differs entirely from any other thus far described. All the nuclei in every cell in the tubule gradually and almost uniformly lose their basophilic staining capacity and become acidophilic, taking the red counterstains. At the same time the cytoplasm of all the cells fuses together and becomes homogeneous in appearance. So that the entire cytoplasm in the tubules finally becomes one single mass, resembling very closely the homogeneous mass of necrotic tissue seen in an infarct. This mass apparently undergoes a process of autolysis, and vacuoles later replace the cytoplasmic substance. This process continues until finally the structure disintegrates and the position of the tubule is indicated by only the membrana propria. In spite of this necrosis in the tubules, the intertubular tissue shows no marked degenerative changes. However, a very irregularly distributed moderate hyperplasia of the interstitial cells is apparent (fig. 14, *D*). While not the typical picture produced by the chronic inanition in group III, this condition evidently corresponds to the advanced degenerative process in an extreme case.

4. Changes in young rats retarded by underfeeding for long periods beginning at three weeks of age (group IV)

In the three rats underfed from three weeks to 223 to 428 days of age (table 1) the body has approximately doubled in

weight, whereas normally it should have increased to about twelve times the initial weight. The testes are likewise of course far below norm for the corresponding age, though apparently considerably above the norm for the younger rats of similar body weight (rats Si 10 and Si 11; also Donaldson's Wistar norm). Stewart ('18), however, concluded that in rats underfed beginning at three weeks of age so as to reach only about 50 grams in body weight at 412 days of age the testes average 42 per cent below normal (for corresponding body weight). It is evident that the changes in the weight of the testis are extremely variable, so it is unsafe to draw general conclusions from only a few cases.

Judging from the size of the tubules in normal testes of similar weight, the tubules in group IV should average above 200μ in diameter. As shown in table 1, however, in three of the four cases the tubules appear subnormal (90 to 120μ) in diameter.

Microscopic sections (stained with haematoxylin and eosin) of the testis show that the size of the tubules in these rats long underfed has considerably decreased. The number of tubules has also decreased and they have become widely separated (fig. 11), due in part to the accumulation of fluid in the interstitial spaces (edematous infiltration). No mature spermatozoa or spermatids appear, although they are present in normal rats of corresponding body or testis weight. Spermatogenesis here (as in group III) has apparently not passed the primary spermatocyte stage. Most of the tubules contain three to four layers of cells, composed of spermatocytes and spermatogonia. The former show the most profound changes. Some appear as shadows without any nucleus or cytoplasm. Others have pycnotic nuclei and a homogeneous cytoplasm. Multinucleated giant-cells are present and the nuclei in these cells show pycnotic changes. Many spermatogonia and all the Sertoli cells appear normal. Mitotic figures are still present. Apparently some vascular changes have taken place. There is a slight sclerosis in the walls of the blood-vessels and also (apparently) a reduced blood-supply to the tubules. There is not any noticeable increase in the quantity of interstitial tissue (proper) (fig. 14, *E*) or any appreciable change in the structure of the interstitial cells, but the quantity of interstitial fluid has enormously increased.

Since all three rats (St 44.1, St 44.4 and St 44.7) show the same histological structure, the question of individual variation may be excluded. So that it appears that the 'growth tendency' so strongly manifested in the testis during inanition in young animals is confined to the formation of the earlier cells in the spermatogenetic cycle; that is, the process can go only to the spermatocyte stage. This is probably what happened in the case of the rats in group III, as before mentioned.

In one rat (M 29.109) inanition was started at ten weeks of age after the testis had presumably reached the stage when mature spermatozoa are produced. Even though kept at maintenance (constant body weight) by extreme underfeeding for 244 days, this testis shows the following histological structure. Most of the tubules are normal in structure and size and show well-developed spermatozoa. However, many lumina are filled with a débris made up almost entirely of heads and tails of spermatozoa. A few tubules show a slight desquamation process, but this is not distributed evenly among the tubules and is probably of no importance. Aside from this, the structure of the testis is apparently normal. Mitotic figures are present and all the various stages of spermatogenesis can be followed out. The conditions in this case emphasize the importance of the age factor. It indicates that if the testis has reached sexual maturity before experimental inanition, the effect upon spermatogenesis is much less marked than in cases where the underfeeding is begun at an earlier period, although the further growth of the testis (in weight) may be hindered. No final conclusions can be drawn from this one rat, however, although the results are in agreement with the conclusions of Jackson and Stewart ('20) as to the importance of the age at which the inanition begins.

5. Changes in adult rats after acute inanition (group V)

As shown in table 1 (group V), adult rats were subjected to acute inanition for periods varying from nine to twelve days. The loss in body weight varies from 30 to 47 per cent. The testes also apparently lose a great deal in weight, but the exact amount can of course be only roughly estimated. The test rats

at the beginning of the experiment varied in body weight from 216 to 328 grams. According to the Wistar norm tables compiled by Donaldson ('15), these body weights call for from 2.5 to 2.8 grams of testis. A comparison with the figures in table 1 shows that at autopsy the testes in weight varied from 1.468 to 2.43 grams, indicating considerable loss in weight. The average diameter of the tubules has correspondingly decreased from over 300μ to an average of 221.5μ. Jackson ('15) found that the loss in weight of the testis of adult rats during acute inanition is nearly proportional to that of the whole body. This agrees in general with the results obtained by Falck ('54), Voit ('66), Manassein ('68), and Gerhartz ('09). An atrophy of the testis relatively much greater than the decrease in body weight during inanition was noted in birds by Grandis ('89), and (during vitamine deficiency) by McCarrison ('19) and Dutcher ('20). A similar result in rats on lipoid-free diet was noted by Hatai ('15).

In one rat (Si 9) which was held for eleven days without food or water, the testis had shrunken away from the tunica albuginea and had decreased considerably in size. This was, however, not apparent upon removing the organ at autopsy, because the intervening space was filled with a fluid, which kept the tunic distended and gave it a normal rounded appearance. This phenomenon has likewise been noted by Allen ('19) in his study of rats subjected to a diet deficient in the water-soluble vitamines.

At first glance, the sections of the testes in this group appear perfectly normal in structure. The majority of the tubules are apparently normal in shape and show no signs of degeneration, as was likewise noted by Simonowitsch ('96). Spermatogenesis appears to be going on as usual. Spermatozoa are abundant and show no alteration in structure. There is no apparent change in the amount or structure of the interstitial tissue.

However, more careful study shows that in each section a few tubules have suffered as a result of the inanition. These tubules, though few in number and placed in immediate relationship with perfectly normal tubules, may show very marked and very severe changes (fig. 12). The spermatozoa are irregular in structure and show extreme degenerative processes. The sper-

matids may present a picture which strongly suggests a true synizesis. This peculiar clumping of the chromatin toward the periphery and toward one side of the nucleus has been described by Monterosso ('12) as a form of degeneration. But I have observed this same structure in almost everyone of my control rats, and believe that we are dealing here rather with a rearrangement of the chromatin material in the normal cytomorphosis of the cell.

The secondary and primary spermatocytes show marked necrobiotic changes. Even the spermatogonia are involved and reveal pycnotic and karyolytic changes in the nuclei. The Sertoli cells are apparently the only ones not severely injured.

Depending on the stage of degeneration, large numbers of multinucleated giant-cells are present in the tubules. These cells each contain from four or five nuclei up to as many as twelve or fifteen nuclei. Some tubules are so atrophic and degenerated that only the membrana propria remains, with a few necrotic giant-cells in the lumina. These giant-cells were carefully studied with special reference to their origin. Apparently they are derived from primary spermatocytes, which fuse together in groups during their desquamation. These cells will be referred to again at a later period.

Desquamation of the epithelial cells in these degenerating tubules is very common and apparently initiates the process of degeneration. This process appears to start with the secondary spermatocytes, but as the sloughing process continues the primary spermatocytes and even the spermatogonia are detached into the degenerating mass in the lumen of the tubule. Degeneration takes place in every case after desquamation has occurred. This degeneration apparently is also always in inverse order to that of spermatogenesis. The spermatozoa are the first to disappear, then the spermatids, followed by the spermatocytes and spermatogonia. The Sertoli cells are the most resistant. This agrees with the results obtained by Monterosso (in starved rats), Bouin and Garnier (in alcoholized rats), and Regaud and Tournade (after ligation of the spermatic cord). Allen ('19) states that (in degeneration due to vitamine deficiency) "the

spermatocytes seem to be the first affected, the spermatids next, and the spermatogonia last."

It therefore appears that acute inanition notably affects but comparatively few tubules in the testis, and that the other tubules retain their normal structure, but all the tubules suffer a loss in size. In spite of a loss of about one-third in the weight of the testis, spermatogenesis apparently continues normally in most of the tubules. But the few tubules which for some unexplainable reason are less resistant show atrophic and necrotic changes which are as marked as any found in chronic inanition.

Likewise, atrophic and degenerative changes in the seminiferous epithelium during inanition have been described by Grandis ('89) in pigeons, Pernice and Scagliosi ('95) in chickens, Simonowitsch ('96) in rabbits and guinea-pigs, Loisel ('01) in the dog, Monterosso ('12) in rat and mouse, and Poiarkoff ('13) in the dog. Similar changes have been described as a result of vitamine deficiency by McCarrison ('19) in pigeons and Allen ('19) in rats.

The extent of the degenerative changes naturally varies in general with the severity of the inanition. In the adult rabbit, Traina ('04) found that spermatogenesis ceases when the loss in body weight reaches about 30 per cent.

There is also a variation according to species, season, etc. At certain periods the testis during inanition may even continue to develop at the expense of the remainder of the body in the salmon (Miescher, '97) and frog (Nussbaum, '06).

6. Changes in rats refed after underfeeding beginning at three weeks of age and extending for various periods (group VI)

In one rat (St 12.53) refed for three and one-half days (table 1), the refeeding period was too short to produce any definite results. There is apparently already some increase in the total body weight, but very little, if any, in the testis. Sections show no definite change from the appearance of the testes in group IV. The primary spermatocytes still show necrotic changes and there is no advance in the stage of spermatogenesis. The

average diameter of the tubules (98.7μ) is slightly below that in rat S 7.32, with similar testis weight.

In another rat (St 10.26), refed for fourteen days after maintenance by underfeeding from twenty-one to seventy-two days, many improvements have taken place. The body weight has increased from around 30 to 86.3 grams, but there is no great increase in the weight of the testes. The reason for this becomes more evident upon histological study. Sections (stained with iron haematoxylin) show no increase in the number and but slight increase in the diameter of the tubules, compared with those of group III. But all the débris has been removed and no degenerating cells are to be seen (fig. 13). No secondary spermatocytes are present. The interstitial cells and their nuclei appear normal (but increased in size). They are, however, definitely increased in number above normal. They are evenly distributed throughout the testis, in this way differing from the condition found by Allen ('19) in the rats of Osborne and Mendel subjected to a diet deficient in the water-soluble vitamines. There are numerous mitotic figures among the spermatocytes and spermatogonia, showing all the stages of the karyokinetic cycle. The blood-vessels are distended with blood. It would appear that all the energy in the testis has been utilized to 'clean up' the waste material and to prepare for a further advance. This may account to some extent for the lack of increase in the weight of the testis.

In the rat (S 12.52) which was refed for thirty-seven days, the weight of the testis has greatly increased and histological study shows that spermatogenesis is going on normally. The tubules are normal in structure and contain many mature spermatozoa. The average diameter of the tubules has, however, increased to 222.7μ, accounting for the increase in weight. The only difference to be found (as compared with normal control testes) is an increase in the amount of interstitial tissue (fig. 14, *F*).

We must distinguish between interstitial tissue and interstitial cells. The former term applies to all tissues outside of the tubules proper; the latter (interstitial cells) refers only to the

specific cells playing a part in the internal secretion of the testes. In reality, there is not so much a general hypertrophy of the interstitial tissue, but rather a hyperplasia of the interstitial cells proper. There is a marked increase in the number of these cells and a slight increase in their size. They assume a more or less cord-like arrangement. The nuclei of the cells are spherical and rather vesicular, although a few clumps of chromatin are always present close to the periphery. A light granular cytoplasm surrounds the nuclei. After the very young stages (one to seven days), mitosis among these cells has never been observed. One possible explanation which may be offered is that mitosis in these cells takes place very rapidly, so that, although cell division occurs, it is rarely found in the sections.

The fourth rat in this group (S 33.118), refed for 206 days, has completely recovered from the effects of the underfeeding and presents a perfectly normal adult histological structure. The diameter of the tubules shows an increase of 291.1μ. Even the interstitial tissue and cells appear normal in quantity and structure.

These results are in accord with the work of Stewart ('15), who found that in rats refed after underfeeding from three to twelve weeks of age, the testes remain somewhat below normal weight for a few weeks, but regain normal weight before the adult stage is reached. In later experiments (Stewart, '18), in which the underfeeding was prolonged, the testis became markedly subnormal in weight (as found by Jackson, '15 a). Jackson and Stewart ('19) reported that the testis, which increases in relative weight in young rats during underfeeding, remains somewhat above normal weight during refeeding to a body weight 25 to 50 grams, but is subnormal in those refed to 75 grams body weight. Finally, Jackson and Stewart ('20) found that when the underfed rats are fully refed to maximum body weight, the testes are definitely above normal for the corresponding body weight. A restoration of the testis to normal structure and function upon refeeding after inanition has likewise been noted by Simonowitsch ('96) in rabbits and guinea-pigs, and by Loisel ('01) and Poiarkoff ('13) in dogs.

DISCUSSION

1. Origin and significance of polynucleated giant cells

It has been claimed by some authors that giant-cells may occur normally in the testis. I have never seen either a polynucleated or a giant-cell in a normal seminiferous tubule. Monterosso ('12) found that these cells are very rare in normal tubules, but occur more frequently during early inanition. He found that their number increases with the length of inanition, and that as many as fifteen nuclei might be seen in a single cell. He believes that they are formed by a fusion of the neighboring cells.

On the other hand, Bouin and Garnier ('00) believe that these cells are formed by an abnormal mitosis of the nuclei within the cell. Allen ('19) noticed these cells during the early stages of degeneration, but offered no explanation as to their origin.

My studies lead me to believe that the multinucleated cell is formed by a fusion of primary spermatocyte cells when they begin to degenerate. As a rule, these cells show marked nuclear and cytoplasmic degenerative changes later than those cells which break off independently and do not fuse with other cells. This suggests that fusion of cells may be a sort of protective measure from the effects of the inanition. De Bruyne ('99), however, claims that these polynuclear cells are precursors of degeneration. No mitotic figures have ever been observed in any polynucleated giant-cell.

2. Mitosis during inanition

As to the occurrence of mitosis during inanition, my own observations agree in general with those of Morpurgo ('88, '89), Grandis ('89), Traina ('04), and others. Traina, for instance, found that mitotic figures persist after a loss in body weight of 30 to 35 per cent. On the other hand, Pernice and Scagliosi ('95), in young chickens on water inanition, and Morgulis, Howe, and Hawk ('15), in fasting dogs, reported an absence of mitosis in the testis. In my adult rats subjected to acute inanition

(S 25, S 26, S 27), with loss in body weight of 30, 35, and 39 per cent, mitotic figures are still present in large numbers. Another rat (Si 9), with loss in body weight of 47 per cent, still shows numerous mitotic figures. They are present even in tubules showing extreme degenerative changes. In young rats underfed from the age three to ten weeks, mitosis is apparently unaffected. Even in those animals in which the underfeeding was continued to 400 days or more, the mitotic figures can be seen in many of the tubules. It would therefore appear justifiable to conclude that it is impossible by inanition to suppress mitosis entirely in the epithelium of the seminiferous tubule. The mitoses, however, may be decreased in number, as found in the rats two days old subjected to acute inanition.

The presence or absence of amitosis in the testis has long been a disputed question. Monterosso ('12) found amitosis present among degenerating spermatocytes and spermatogonia. Allen ('18, '19) believes that amitosis does not occur. I have likewise never seen a definite case of amitosis in any of my sections.

3. Interstitial tissue during inanition

Some investigators mention the increased quantity of interstitial tissue, which is occasioned by any degeneration or atrophy of the seminiferous epithelium. Cordes ('98) found an increase in interstitial tissue in cases of chronic disease with cachexia. Kyrle ('10) and Voss ('13) pointed out that in diseased conditions and in underdeveloped testes, the tubules are far apart and the interstitial tissue surpasses the tubules in amount. Allen ('19) also found an increase in the quantity of interstitial tissue in rats fed upon a diet deficient in water-soluble vitamines.

In my own series of albino rats, there appears in no case any demonstrable increase in interstitial tissue during either acute or chronic inanition. However, in those rats which were refed after various periods of underfeeding (group VI), there is a gradual increase in the relative amount of interstitial tissue (interstitial cells) until the gland regains its normal size and structure. Thereafter, the interstitial tissue apparently de-

creases in amount until it reaches the normal proportion. That is, the interstitial cells appear relatively increased in number only during the regenerative period.

Measurements of the nuclei of interstitial cells indicate that there is a sharp decrease in the average diameter of the nucleus from 7.1μ at birth to 4.7μ at three weeks of age. From the three-weeks stage there is very little change in the size of the nucleus. Comparison with the test groups indicates that the size of the nucleus of the interstitial cells is not affected to any marked degree by the inanition tests. In group III, two of the three specimens measured show a decreased average diameter of the nucleus (in underfeeding from five to ten weeks of age); and in group VI, it would appear that refeeding causes some increase in the size of the nucleus, in addition to the numerical increase already noted. There is considerable individual variation, however, and the number of observations is insufficient to warrant final conclusions.

SUMMARY

The results of the present investigation may be summarized as follows:

1. In the normal testis of the albino rat during the first postnatal week the (solid) seminiferous tubules consist of a single layer of parietal cells ('Sertoli cells' of v. Ebner) and a few central cells ('Ursamenzellen' of v. Ebner). After the first week, the normal postnatal development of the testis and the process of spermatogenesis proceed essentially as described by Allen ('18).

2. In rats two days old starved for forty-eight to fifty hours, the testis increases markedly in weight, but mitoses are reduced in number and the normal process of histological differentiation is arrested. The seminiferous tubules remain nearly normal in diameter.

3. During underfeeding for various periods beginning in rats three weeks old, mitosis continues in the cells of the seminiferous tubules, but the process of spermatogenesis is arrested at the primary spermatocyte stage, which persists even in rats over

400 days old. The spermatocytes degenerate and are resorbed, but if the number formed exceeds those destroyed, the testis may increase in weight. Multinucleated giant-cells are formed during the process of degeneration. The spermatogonia and Sertoli cells usually persist unaffected, except in very extreme cases, where a complete degeneration and disintegration of the seminiferous epithelium may occur. If the underfeeding begins after sexual maturity, the seminiferous tissue is much more resistant and normal spermatogenesis may persist for a long time. The seminiferous tubules may increase slightly in diameter in the shorter tests, but usually appear subnormal in size in the longer experiments.

4. Acute inanition in adult rats, with 30 to 47 per cent loss in body weight, produces degenerative changes in a few, irregularly scattered, tubules. All the other tubules show apparently normal structure and spermatogenesis, although there is a general decrease in their size. The degenerative changes are initiated by a desquamation of the epithelial cells into the lumen of the seminiferous tubule, followed by pycnosis and karyolysis. The process involves first the spermatids and spermatozoa, then the secondary and primary spermatocytes, and finally the spermatogonia. The Sertoli cells are the most resistant. During the degenerative process, multinucleated giant-cells arise, apparently by fusion of the degenerating spermatocytes.

5. During inanition, mitosis is very persistent in the seminiferous epithelium, both in young and adult rats. It may occur even in tubules where nearly all the cells are more or less degenerated. Amitosis was not observed. A condition resembling synizesis was frequently observed in the spermatids in both controls and test rats.

6. Refeeding after prolonged inanition (beginning in rats at three weeks of age and extending to twelve to twenty weeks) results in a rapid improvement in the structure of the testis, although it may lag behind in weight for a while during the preliminary stages of reconstruction. Spermatogenesis returns to normal in a short time, the tubules gradually increase to normal diameter, and spermatozoa appeared in thirty-seven days.

7. There is a definite hypertrophy of the interstitial tissue and an increase in the number of interstitial cells of the testis during the regenerative period on refeeding after inanition (in growing rats). No hypertrophy of the interstitial tissue was found accompanying atrophy of the seminiferous epithelium during inanition in either young or adult rats. The structure of the interstitial tissue and the size of the nuclei apparently remain nearly normal during acute and chronic inanition, except in extreme cases, where degenerative changes in the cells may occur.

FIGURES AND EXPLANATION

The drawings were made with the aid of a camera lucida. The unit of magnification is 630 diameters for all the figures, with the single exception of figure 10, which has a magnification of 127 diameters. All the material stained with Heidenhain's iron-alum haematoxylin had been fixed in Carnoy's fluid (no. 1). The remaining material had been fixed in either Bouin's or Zenker's fixatives.

PLATE 1

EXPLANATION OF FIGURES

Figures 1 to 7 show normal development in the epithelial wall and the growth of the tubules in albino rats from birth to eight weeks of age. All × 630.

Figures 8 to 13 show changes in the seminiferous epithelium and size of the tubules brought about by experimental conditions.

1 Transverse section of a tubule from the testis of a normal newborn rat (Si 1.1). Section 6μ thick; stained with iron-alum-haematoxylin and acid fuchsin. × 630. Note the presence of a single layer of parietal cells, *P.C.*, and the large central cells, *C.C.*, in the center of the tubule. Each tubule is surrounded by a membrana propria, *M.P.*

2 Transverse sections of a tubule from the normal testis at four days (Si 2.5). Section 6μ thick; stained with iron-alum-haematoxylin. × 630. The number of parietal cells, *P.C.*, has increased, while the central cells, *C.C.*, are less frequent. Membrana propria, *M.P.*

3 Transverse section of a tubule from the normal testis at seven days (Si 1.3). Section 6μ thick; stained with iron-alum-haematoxylin. × 630. Mitotic activity is apparent. A spermatogonium in metaphase is well shown, *Sp.C.* Germinative cells are all alike (Allen's type A). Membrana propria, *M.P.*

4 Section of a tubule from the normal testis at fourteen days (Si 1.5). Section 6μ thick; stained with iron-alum-haematoxylin and acid fuchsin. × 630. Cells of (Allen's) types A and B are abundant and a few cells of type C are present, *A.*, *B.*, *C.* Sertoli cells, *S.C.*, are beginning to assume their adult position and structure. Membrana propria, *M.P.*

5 Section of a tubule from a normal testis of twenty-one days (Si 6.0). Section 10μ thick; stained with iron-alum-haematoxylin. × 630. All types of cells, *A.*, *B.*, and *C.*, are present. Primary spermatocytes, *P.S.*, have appeared. Sertoli cells, *S.C.* Membrana propria, *M.P.* Note the formation of a lumen, *L.*, in the tubule.

EXPLANATION OF FIGURES

6 Section of a tubule from a normal testis at four weeks (K 8.1). Section 10μ thick; stained with iron-alum-haematoxylin. × 630. Presents the same picture as the preceding figure, but also shows a marked increase in the number of primary spermatocytes, *P.S.*

7 Portion of a transverse section of a tubule from a normal testis at eight weeks (St 5.2). Section 10μ thick; stained with iron-haematoxylin. × 630. Note the gradual transition from the spermatogonia to the mature spermatozoa. This corresponds very closely to the condition found in the adult testis. Sertoli cell, *S.C.*; spermatogonia, *S.*; primary spermatocytes, *P.S.*; secondary spermatocytes, *S.S.*; spermatids, *Spt.*; spermatozoa, *Sp.*; membrana propria, *M.P.*

8 Section of three tubules from the testis of a rat four days old (Si 2.6) which had been subjected to acute inanition for fifty hours. Section 6μ thick; stained with iron-alum-haematoxylin and acid fuchsin. × 630. Note that the structure resembles that of the newborn more closely than that normal at four days. Compare with figures 1 and 2. Central cells, *C.C.*; parietal cells, *P.C.*; membrana propria, *M.P.*

PLATE 3

EXPLANATION OF FIGURES

9 Section of a tubule from a rat (S 7.32) held at constant body weight by underfeeding from three to ten weeks of age. Section 6μ thick; stained with haematoxylin and eosin. $\times$ 630. Degenerating primary spermatocytes, *D.P.S.*, showing the homogeneous, deeply acidophilic staining reaction of the cytoplasm. Note the persistence of mitotic figures, *M.F.*; the normal Sertoli cells, *S.C.*, and spermatogonia, *S.* A multinucleated cell, *Mu.C.*, typical of those appearing as a result of chronic inanition. Degenerating cytoplasm, *D.C.*; membrana propria, *M.P.*

10 Section of a portion of the atrophic testis from a rat (S 11.65) subjected to chronic inanition from three to ten weeks of age. Section 10μ thick; stained with haematoxylin and eosin. $\times$ 127. The central tubule shows the extreme stage of degeneration (described in text), a complete nearly homogeneous mass of necrotic tissue. The surrounding tubules show various stages of degeneration. Note the mitotic figures, *M.F.*, in the tubule to the right and the apparently normal Sertoli cells, *S.C.* A slight hyperplasia of the interstitial cells, *I.C.*, appears. Blood-vessel, *B.V.*

11 Portion of a tubule from the testis of a rat (St 44.4) stunted by underfeeding from three weeks to 428 days of age. Section 10μ thick; stained with haematoxylin and eosin. $\times$ 630. Note the degenerating primary spermatocytes, *D.P.S.*; the multinucleated cell, *Mu.C.*, in the lumen. Sertoli cells, *S.C.*, and spermatogonia, *S.*, are apparently normal. Membrana propria, *M.P.*

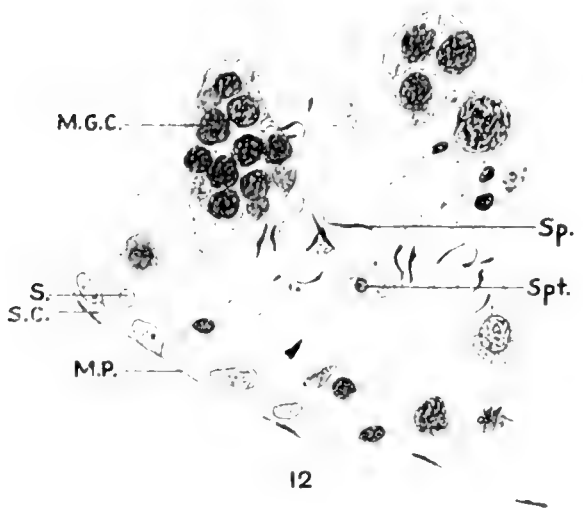
PLATE 4

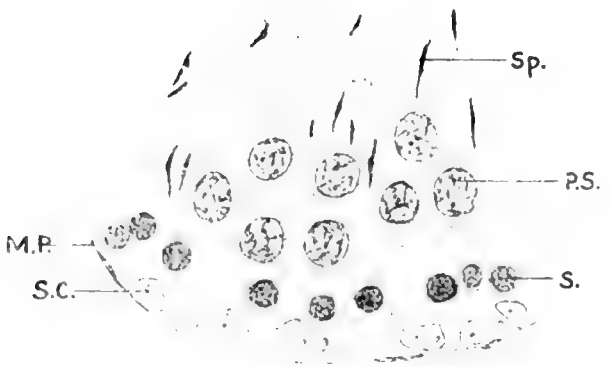
EXPLANATION OF FIGURES

12 Oblique section of a testis from an adult rat (S 25) subjected to acute inanition for nine days. Section 10μ thick; stained with haematoxylin and eosin. × 630. Multinucleated giant-cells, *M.G.C.*, occupy the center of the tubule. Débris composed of degenerating cells of various kinds fills the tubule. Spermatozoa, *Sp.*; spermatids, *Spt.*; spermatogonia, *S.*; membrana propria, *M.P.* The Sertoli cells, *S.C.*, still occupy their normal position, but show atrophic and degenerative changes.

13 Portion of transverse section of the testis from a rat (S 12.52) underfed from three to ten weeks of age and then refed for thirty-seven days. Section 7μ thick; stained with haematoxylin and eosin. × 630. Note the large number of normal primary spermatocytes, *P.S.*, and spermatozoa, *Sp.* Spermatogonia, *S.*, showing mitotic figures, are abundant. Sertoli cell, *S.C.*; membrana propria, *M.P.*



12



13

PLATE 5

EXPLANATION OF FIGURES

14 A to F represent various stages in the interstitial (mesenchymal) cells of the testis during normal development, inanition, and refeeding. All magnified × 630. *A*, normal newborn (Si 1.4). *B*, normal adult (S 14). *C*, underfeeding, three to ten weeks of age (S. 7.32). *D*, extreme atrophy in underfeeding from three to ten weeks of age (S 11.65). *E*, underfeeding from three weeks to 428 days of age (St. 44.4). *F*, refed thirty-seven days after underfeeding from three to ten weeks of age (S. 12.52).

Resumen por los autores Bradley M. Patten y Rees Philpott.
Western Reserve University, School of Medicine.

La contracción de los embriones durante los procesos preparatorios a la obtención de cortes.

Para averiguar el grado de contracción producido al fijar material embriológico y prepararle para la obtención de cortes, los autores han llevado a cabo varias series de medidas en embriones de cerdo durante los diversos momentos de algunos de los procederes comunes. Los fijadores usados fueron los siguientes: Licores de Zenker, Orth, y Tellyesnicky; formol al 10%, formal-alcohol y licor de Bouin. Primero se midió la longitud del embrión desde la curvatura cefálica hasta la lumbar, cuando aquél estaba aún contenido en el líquido amniótico, y después a raíz del uso de cada una de las soluciones con que fué tratado. La contracción media fué medida en tantos por ciento de la longitud primitiva del embrión. Estas medidas fueron representadas gráficamente por curvas que indican el grado de contracción en cada uno de los momentos de la técnica empleada. La mayor contracción aparece después de la fijación con los líquidos que contienen bicromato, tales como los licores de Zenker, Orth y Tellyesnicky, y la disminución de la longitud del embrión varía desde el 30% en embriones de 10 mm. hasta próximamente el 20% en los embriones de 20 a 25 mm. El grado mayor de contracción en los embriones más jóvenes debe probablemente atribuirse a la menor compacidad de su mesodermo. La mayor parte de la contracción en estos métodos es causada por los fijadores. La fijación en formol al 10% y en formol alcohol produce un hinchamiento inicial, al cual sigue una contracción rápida durante la deshidratación. La contracción total después de la inclusión en parafina es próximamente igual á la producida por las soluciones de bicromato. La contracción después del licor de Bouin es ligera, pero continúa durante la deshidratación e inclusión. La contración total con este método es algo menor que la de los fijadores que contienen bicromato. La comparación de las diferentes gráficas indica una tendencia mayor hacia el aumento de la contracción durante la deshidratación despues de los fijadores que producen menos contracción inicial. Esto prácticamente anula, por los menos en el caso del material destinado a la inclusión en parafina, las supuestas ventajas de los fijadores mezclados con el fín de evitar la contracción por el fijador mismo.

THE SHRINKAGE OF EMBRYOS IN THE PROCESSES PREPARATORY TO SECTIONING

BRADLEY M. PATTEN AND REES PHILPOTT

Laboratory of Histology and Embryology of Western Reserve University, School of Medicine

EIGHT FIGURES

INTRODUCTION

The true or fertilization age of the human embryos which come into the laboratory is usually uncertain if not altogether unknown. For the most part the age of other mammalian embryos used for laboratory study is equally a matter of conjecture. For this reason it is customary to designate the stage of development attained by an embryo by giving its measurements. In this country the method of measuring embryos used by Mall is in quite general use (Keibel and Mall, '10, vol. 1, ch. 8).

If embryos always came into the hands of the investigator fresh, so that the measurements might be made under uniform condition, the methods in use would leave little to be desired, at least as far as establishing a basis for comparing different embryos is concerned. Unfortunately, however, embryos are brought into the laboratory in various stages of preservation or lack of it. The shrinkage of embryos under the various treatments to which they are subjected for preservation and in preparation for sectioning makes the comparison of embryos measured at different steps in the processes a precarious matter.

While the fact that shrinkage is to be expected is a matter of common information, we have been unable to find in the literature any quantitative data covering the shrinkage which is to be encountered in the various processes of fixation commonly in use for embryological material. The measurements

described in this paper were made to ascertain how much shrinkage occurs in the various steps of some of the more common methods of preserving embryos and preparing them for sectioning. Because linear dimensions are already in use as a criterion of the stage of development attained, they were used, rather than weight or volume, as a basis for determining the shrinkage. It is hoped that these measurements and the further accumulation of similar data will aid in more accurate comparisons of embryos which come into the hands of investigators in widely different stages and conditions of preservation.

MATERIAL AND METHODS

By reason of the readiness with which they could be secured fresh, and because of their close comparability with young human embryos, pig embryos were used for the entire series of measurements.

The embryos were measured first in amniotic fluid,[1] immediately on removal from the uterus. The measurements made were for the crown-rump length. The belly thickness was also measured in quite an extensive series as a check against the possibility that distortion of the spinal axis might be affecting the length measurements. Inasmuch as the shrinkage in per cent of the original dimensions corresponded fairly closely in the two cases, only the crown-rump measurements are here recorded. All the measurements were made with micrometer calipers graduated in millimeters and indicating the tenths of a millimeter by vernier.

In the early part of the work both of us measured the same embryos independently and compared our results. Our measurements tallied so consistently to the tenth of a millimeter that in the latter part of the series measurements were made by only one observer.

After the first measurement in the amniotic fluid, embryos were measured after each solution with which they were treated.

[1] Some embryos were measured also in physiological saline solution and their measurements compared with those made in the amniotic fluid. The measurements in the two fluids were identical.

Following paraffin infiltration the embryos were transferred from the molten paraffin to xylol for measurement, after which they were at once returned to paraffin for a few minutes before embedding. This process proved to be in no way detrimental to the infiltration or embedding.

Measurements were later carried out on several series of sagittal sections made from the embryos measured during the preliminary processes of preparation. When care is used in expanding the sections on the slide, their measurements correspond to the measurements made subsequent to paraffin infiltration.

MEASUREMENTS

Since the processes to which the embryos were subjected, and therefore the series of measurements made on them, differ in accordance with the fixing fluid, the data secured may be most simply presented under the heading of the fixing agent used.

Zenker's fluid (formula as given in Lee, '13)

The technique employed was not different from that commonly used with Zenker's fluid: twenty-four hours in fixative; overnight washing in running water; about four hours in each grade of the ascending alcohols up to 70 per cent; twenty-four hours in 70 per cent alcohol containing Lugol's solution for the removal of any remaining mercuric chloride; overnight in 95 per cent alcohol; four hours in absolute (two changes); three hours in xylol; two to three hours in soft, and two to three hours in hard paraffin, according to the size of the embryos.

The measurements made on Zenker-fixed embryos are given in detail in table 1 and summarized graphically in the curve of figure 1. To facilitate comparisons for variability, the material in table 1 has been arranged in the order of the lengths of the embryos when measured fresh in the amniotic fluid. It will be seen that while there is, as would naturally be expected, some individual variability, the range of the variation is small. Indeed, comparison of the measurements made on embryos of like original

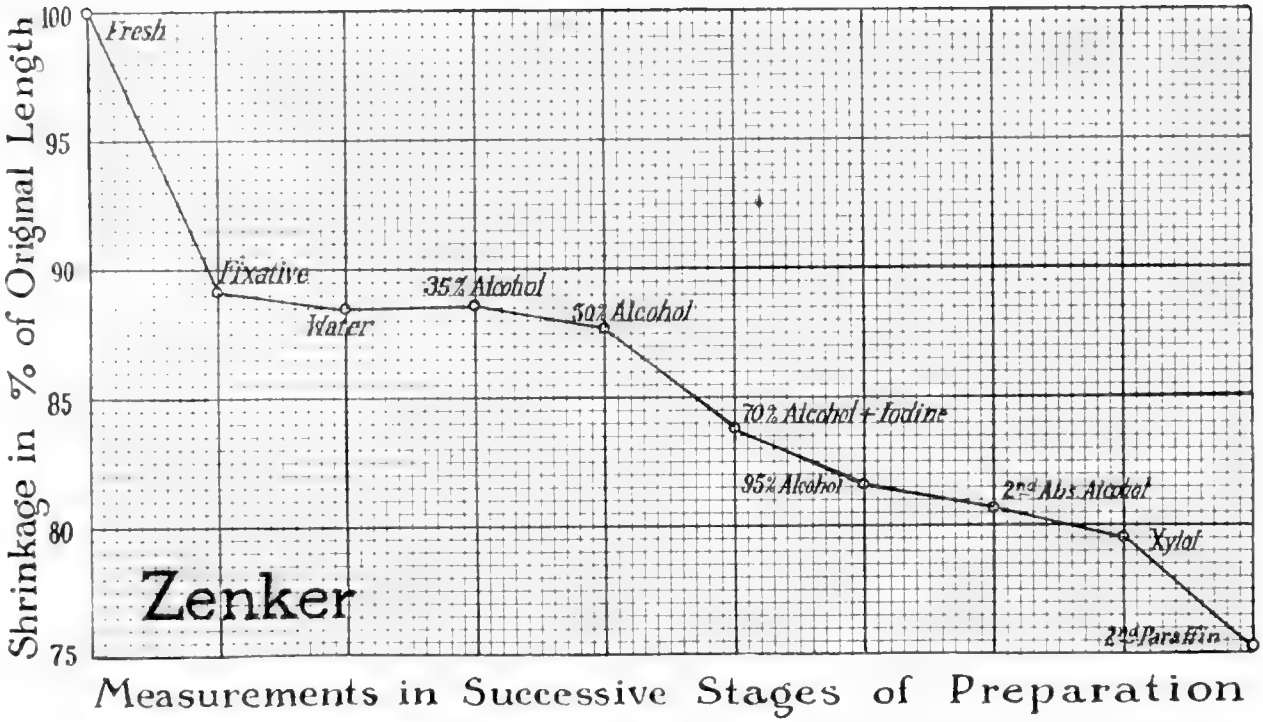

Fig. 1 Graph showing the shrinkage induced in pig embryos by the various solutions with which they are treated in the Zenker method of preparing material for sectioning. The extent of the shrinkage is indicated by expressing the embryos' length at various steps in the process as a per cent of their length when fresh. The points on the curve are located from the average measurements of twenty-eight embryos. The embryos when fresh ranged from 9 to 27 mm. in crown-rump length (average length fresh 16.1 mm.). Individual measurements for the same group of embryos are given in table 1.

length (e.g., embryos from 11.9 mm. to 12.2 mm., table 1) shows their shrinkage at various steps in the process to be surprisingly uniform.

The arrangement of the measurements in order of the original length of the embryos brings out another point. The total shrinkage is greater in the younger embryos than in the older. While it would be unsafe to draw any final conclusions from data based on embryos of the limited size range here studied, it seems probable that this difference in shrinkage is due largely to the differences in the organization of the developing muscular and connective tissues. In embryos of about 10 mm. the mesodermal tissues are represented for the most part by loosely aggregated cell masses with abundant interstitial spaces. By the time the embryo has attained a length of 20 to 25 mm. the cells of the developing muscular and connective tissues have become much more compact with a corresponding reduction of the interstitial spaces. Moreover, in the older embryos chondrification has begun in many centers and renders the body of the embryo more rigid as well as more compact. These conditions would seem quite sufficient to account for the fact that fixation and dehydration of very young embryos result in a greater shrinkage than that induced in older embryos.

The extent to which shrinkage varies with the original length of the embryo is shown graphically in figure 2. The curve is not as precisely indicated as it would be by a larger number of cases, but its general course is nevertheless quite apparent. Only measurements of embryos fixed in bichromate fluids were used in plotting this curve since their shrinkage is closely comparable, whereas some of the other fixing fluids show quite different shrinkage curves.

It was thought possible that preliminary coagulation of embryos by treatment in hot water might reduce the amount of shrinkage they suffered. To test this possibility, embryos were immersed for five minutes in water of 65°C. and then put through the routine Zenker process. As will be seen by comparing the curves of figures 1 and 3, this preliminary treatment with hot water proved to be ineffective in reducing the amount of shrinkage.

Fig. 2. Curve showing the extent to which the total shrinkage of embryos during preparation for sectioning varies with the size of the embryo. Each point is located from the measurements of a single embryo.

Fig. 3. Graph showing the shrinkage induced in pig embryos by the various solutions to which they were subjected in the Zenker method modified by treatment for five minutes with water at 65° C. just before immersion in Zenker. The curve is based on the average measurements of fifteen embryos having an average original length of 18.6 mm.

The slightly less extensive shrinkage shown by the embryos treated with hot water before fixation, if significant at all, is attributable rather to the fact that their average length (18.6 mm.) was somewhat greater than the average length (16.1 mm.) of the embryos treated by Zenker alone.

Orth's fluid (formula as given in Lee, '13)

The technique employed with embryos fixed in Orth's fluid and the times the embryos were allowed to remain in the different solutions were essentially the same as that described for Zenker's solution except for the omission of the iodine treatment. The results of the measurements were tabulated as for the embryos fixed in Zenker, but since the measurements were of the same character as those given in table 1 they have not been given in detail. Figure 4 summarizes the results graphically.

The presence of formalin in Orth's fluid might be expected to lessen the shrinkage to a certain extent. Such is apparently the case, for the shrinkage in this fixative is noticeably less extensive than that in Zenker (compare fig. 4 with figs. 1 and 3). When, however, we follow out the curve, we find that the advantage is only temporary. There is a greater shrinkage in dehydration following fixation by Orth than in dehydration following Zenker fixation. The total shrinkage encountered in the two techniques is virtually identical. The transitory nature of the swelling effect of formalin fixation when it is followed by dehydration is shown much more strikingly by the data given below for formalin uncombined with other solutions.

Tellyesnicky's fluid (formula as given in Minot, '11)

The technique following fixation in Tellyesnicky's fluid was similar to that used for Zenker and Orth material. The results of the measurements are summarized in the curve of figure 5. The slightly smaller amount of shrinkage indicated on the Tellyesnicky curve as compared with the other bichromate fixatives is not sufficient to be regarded as significant. Both as regards the total amount of shrinkage induced and the stage of the process

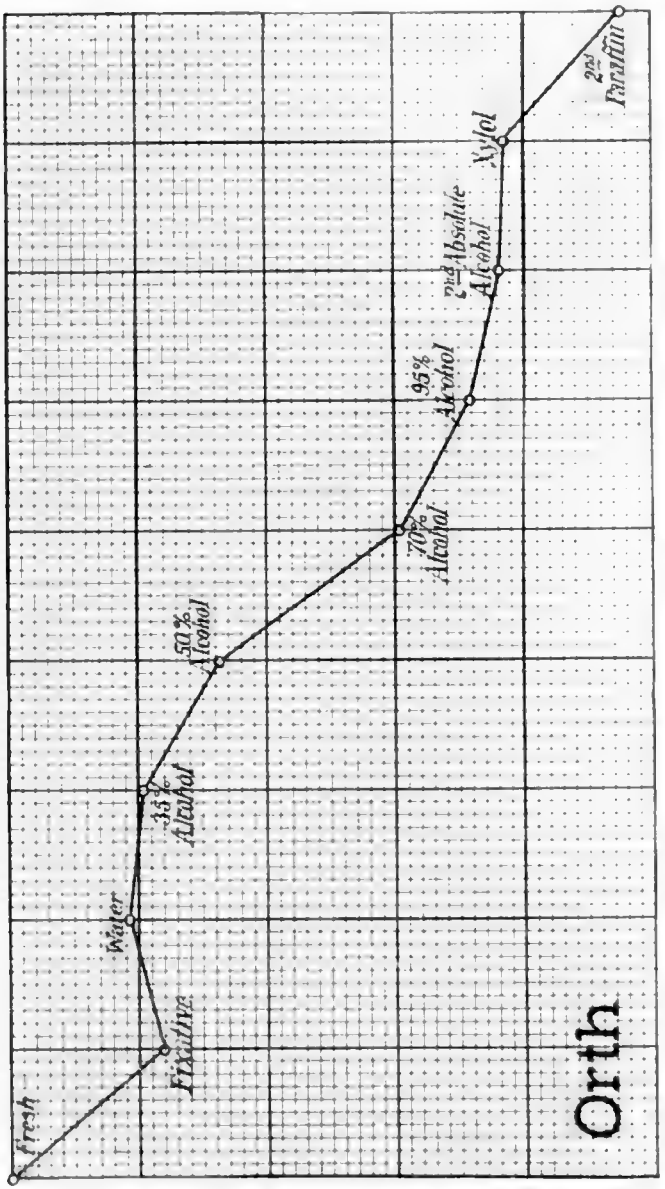

Fig. 1. Graph showing the shrinkage induced in pig embryos following fixation in Orth's fluid. The points on the curve were located from the average measurements of twenty-one embryos averaging 19.7 mm., original length.

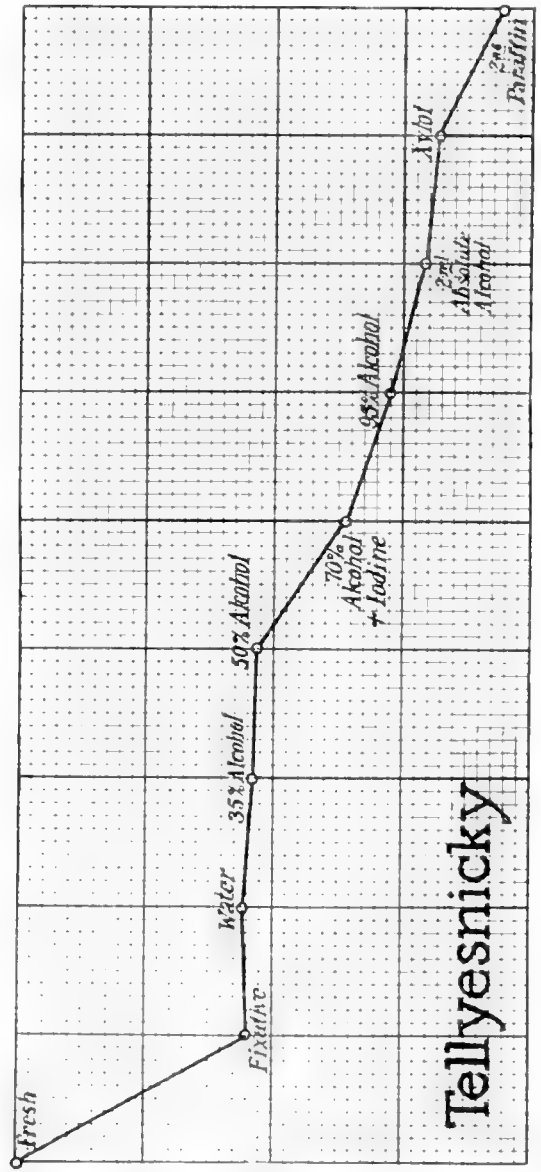

Fig. 5 Graph showing the shrinkage induced in pig embryos following fixation in Tellyesnicky's fluid. The points on the curve were located from the average measurements of twenty-four embryos, averaging 18.3 mm., original length

at which the shrinkage takes place, Tellyesnicky, Orth, and Zenker material behave essentially alike.[2]

Formalin (10 per cent commercial formalin)

Embryos were fixed in formalin for twenty-four hours, transferred to 70 per cent alcohol overnight, left in 95 per cent alcohol twenty-four hours, in absolute (two changes) four hours, in xylol three hours, in soft paraffin two to three hours, and in hard paraffin two to three hours, according to their size.

The measurements of the embryos at various stages in the process are given in detail in table 2 and summarized in the graph of figure 6. The most striking thing that the measurements for formalin fixed embryos bring out is the fact that the initial swelling induced by the formalin is not only rapidly lost on treatment with alcohols, but gives way to marked shrinkage. In fact, the shrinkage of formalin-fixed material during dehydration is more extreme than the shrinkage encountered in dehydration following the other fixatives we used. While, therefore, formalin fixation causes an initial swelling, the ensuing processes of dehydration and infiltration result in a final shrinkage which is approximately the same as that in the bichromate processes.

Schultz ('19) found for foetuses, as did Hrdlièka ('06) and King ('13) for brain material, that the initial swelling effect of formalin fixation tended to become less marked with continued storage in formalin. Although long periods in formalin reduced the initial swelling, it still left their material increased in weight as compared with its fresh condition, producing nothing approaching the shrinkage we found to be caused by dehydration of formalin-fixed embryos.

In regard to dimensions, Schultz found considerable variability, some measurements showing a slight decrease and others

[2] For adult brain material Donaldson ('94), King ('10), and Plant ('18) found an increase in weight and volume following treatment with bichromate solutions. This is in marked contrast to our findings for embryos. The difference between adult brain tissue with its compactness and high myelin content and young embryos with their loosely organized structures might possibly account for their divergent reaction in fixatives.

* All the embryos in this series were measured both for crown-rump length and belly thickness. For the most part the per cent of shrinkage for the two methods of measurement corresponded very closely. In the case of the embryos indicated in the table with an asterisk these two measurements showed unusual divergence. For this reason the shrinkage figures given for them are the mean of the crown-rump and belly shrinkage. All other values are for crown-rump measurements.

a slight increase after storage in formalin. The great difference in the age of the embryos he worked on, as compared with those we dealt with, makes it inadvisable to attempt a direct comparison of our results.

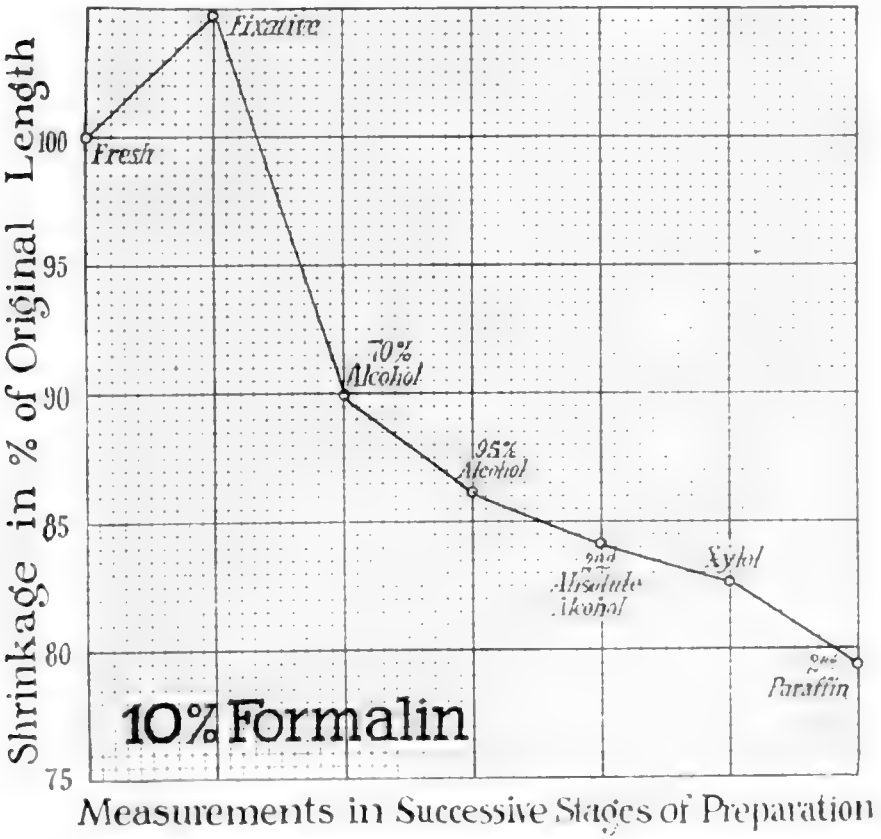

Fig. 6 Graph showing the shrinkage induced in pig embryos following fixation in 10 per cent formalin. The points on the curve were located from the average measurements of twenty-two embryos, averaging 17.7 mm., original length. Individual measurements for the same group of embryos are given in table 2.

Formol-alcohol

There are various mixtures of formalin and alcohol in use as fixatives. The formula we used was:

Formalin, (commercial)	100 cc.
Alcohol, 95 per cent	450 cc.
Acetic acid (glacial)	20 cc.
Distilled water	430 cc.

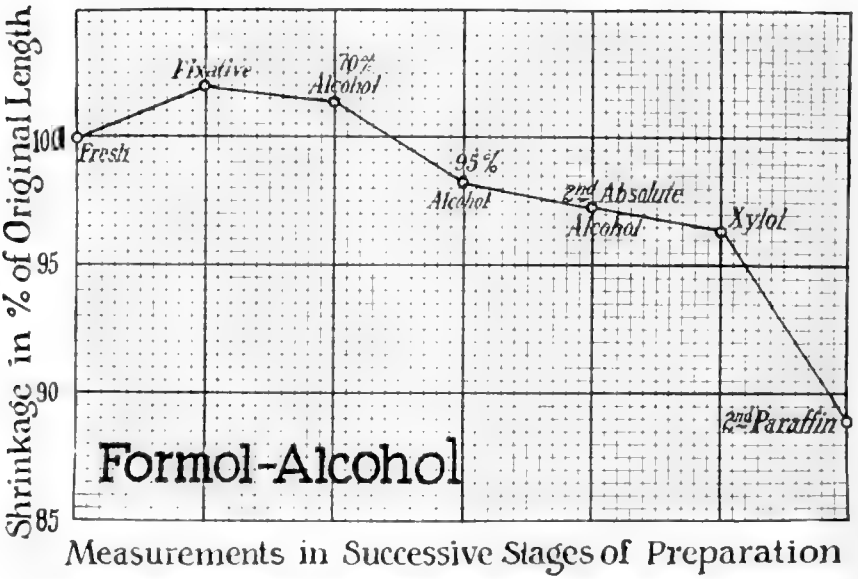

Fig. 7 Graph showing the shrinkage induced in pig embryos following fixation in formol-alcohol. The points on the curve were located from the average measurements of twenty-six embryos, averaging 19.8 mm., original length.

The technique used following formol-alcohol was similar to that given above for 10 per cent formalin. The results of the measurements are summarized in the curve of figure 7.

In embryos of the age range we worked with there was a slight initial swelling produced. This swelling was by no means as marked as that in 10 per cent formalin and could probably be altogether done away with by using more alcohol in the fixative.

The curve of figure 7 would seem to indicate that preservation of gross material with virtually no distortion from its fresh

measurements could be secured by storing material in alcohol of about 80 per cent. However, further work on this point is necessary, because, as the results of Schultz referred to above clearly show, long-continued storage in a preservative may result in unexpected changes in dimensions.

As a fixative for material to be used for histological purposes, little can be claimed for formol-alcohol. While the distorting effect of the fixative itself could undoubtedly be nullified for embryological material of a given stage as was done by Parker and Floyd ('95) for nervous tissues, there would still remain the very considerable shrinkage in dehydration and infiltration. It is true that the total shrinkage in the formol-alcohol technique, as indicated by the graph of figure 7, is somewhat less than in the bichromate fixatives, but the slight advantage on that score is more than counterbalanced by its marked inferiority as a preservative of cytological detail.

Bouin's fluid (formula as in Lee, '13)

Embryos were fixed in Bouin fifteen to eighteen hours, transferred to 70 per cent alcohol for four hours, and then to 95 per cent alcohol for twenty-four hours for hardening. After hardening they were run back through the alcohols and washed in running water overnight, and then run up to absolute, being left four hours in each of the ascending alcohols. The removal of the picric acid by this method instead of by 70 per cent alcohol was done as a matter of economy of alcohol. Except where a large quantity of material is being handled, it is without advantage. With the preliminary hardening in 95 per cent alcohol it appeared to have no deleterious effect on the fixation.

The measurements for Bouin material are summarized in figure 8. The shrinkage in the fixative is very slight (average 2.5 per cent) and in the remainder of the process is gradual and not excessive. The total shrinkage of embryos in the Bouin technique is considerably less than that encountered in the more usually employed bichromate fixatives. The preservation of cytological detail by Bouin is in no way inferior to that secured

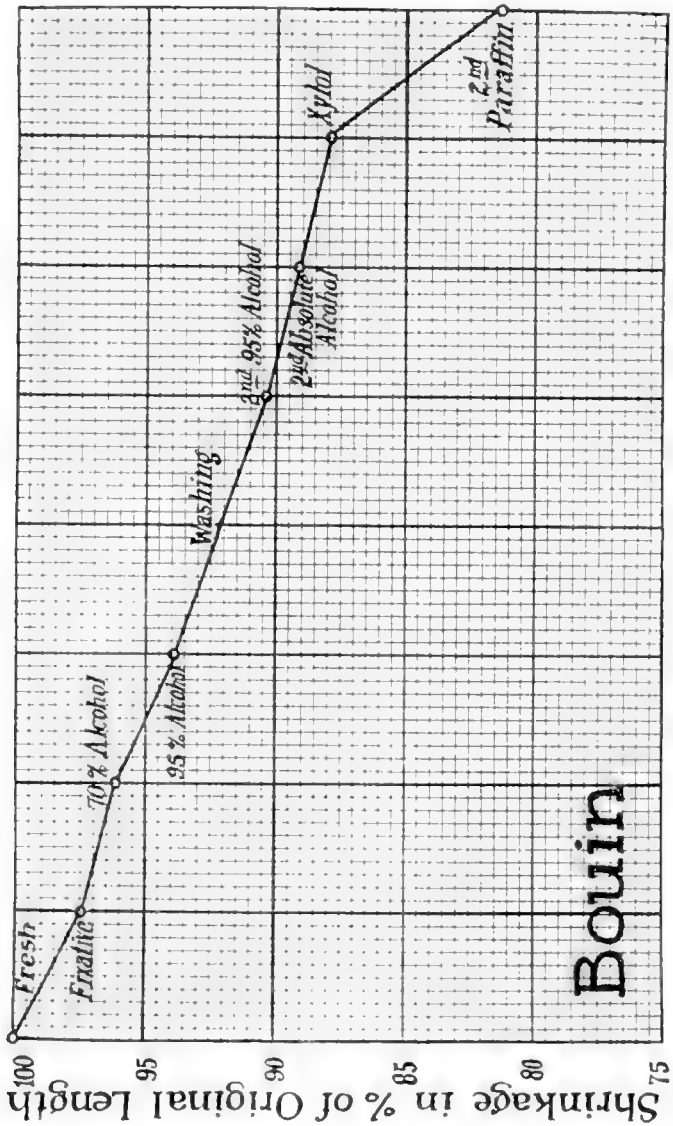

Fig. 8 Graph showing the shrinkage induced in pig embryos following fixation in Bouin's fluid. The points on the curve were located from the average measurements of twenty-three embryos, averaging 19.8 mm., original length.

by Zenker, Orth, or Tellyesnicky, and greatly superior to that secured by formalin or formol-alcohol. As to favorability for staining, Bouin material, if thoroughly washed, leaves little to be desired.

SUMMARY AND CONCLUSIONS

To ascertain the amount of shrinkage which is induced by preserving embryological material and preparing it for sectioning, series of measurements were made on pig embryos covering each stage of some of the common techniques.

The fixatives used were: Zenker, Orth, Tellyesnicky, 10 per cent formalin, formol-alcohol, and Bouin. The crown-rump length of the embryos was measured first in the amniotic fluid, and thereafter following each solution with which they were treated. The average shrinkage was computed in per cent of the original length of the embryo. From these averages graphs were plotted to show the shrinkage encountered at each step of each of the techniques used.

The shrinkage in the bichromate fixatives, Zenker, Orth, and Tellyesnicky, was the greatest encountered, the decrease in crown-rump length ranging from about 30 per cent in 10-mm. embryos to about 20 per cent in 20- to 25-mm. embryos. The more extensive shrinkage in the younger embryos is probably attributable to the less compact condition of their mesoderm. The greatest part of the shrinkage in these techniques came in the fixatives themselves.

Fixation in 10 per cent formalin resulted in an average increase in crown-rump length of about 5 per cent, which was, however, followed by rapid shrinkage during dehydration and infiltration. The total shrinkage of formalin material by the time it was embedded in paraffin was scarcely less than that for material fixed in the bichromate solutions. Histologically, the formalin-fixed material was distinctly inferior.

Formol-alcohol fixation resulted in a slight initial swelling, which was followed by marked shrinkage in dehydration and infiltration. The total shrinkage was somewhat less than that encountered in the bichromate fixatives, but the histological condition of the material was not as good.

Embryos treated with Bouin's fluid showed very slight shrinkage in the fixative. A gradual shrinkage continued, however, during dehydration and infiltration. The total shrinkage in the process was somewhat less than that following the bichromate solutions, and the histological condition of the material and its stainability were fully as satisfactory.

Comparison of the graphs for the several techniques shows:

1. There is a general tendency for the shrinkage in dehydration to be greater in the processes where the shrinkage in the fixative is less. This practically nullifies, as far as material for sectioning is concerned, the supposed advantages of a mixture such as formol-alcohol which is compounded to avoid shrinkage in the fixing fluid itself.

2. There is an abrupt increase in shrinkage during paraffin infiltration which is about the same for all the techniques used. This shrinkage encountered in molten paraffin would in all probability not occur in celloidin embedding, and would be largely reduced by the use of the celloidin-paraffin or chloroform-paraffin method of infiltration.

The crown-rump length of subsequently prepared sagittal sections showed no change from the crown-rump length of the embryo from which they were cut, as measured after paraffin infiltration.

Resumen por el autor, Charles H. Miller.
Carnegie Institution of Washington.

Demonstración del esqueleto cartilaginoso en los fetos de los mamíferos.

Se pueden obtener demonstraciones muy satisfactorias del esqueleto cartilaginoso de los fetos de los mamíferos (hombre, cerdo y mono), de 20 a 150 mm. de longitud, conservados en formol o alcohol, si se tiñen con azul de toluidina, decolorando con alcohol ácido y aclarando con hidrato potásico, pudiéndose conservar de un modo permanente en glicerina los ejemplares así tratados. Ejemplares conservados a la luz durante dos años no presentan indicación alguna de decoloración.

DEMONSTRATION OF THE CARTILAGINOUS SKELETON IN MAMMALIAN FETUSES

CHARLES H. MILLER

Department of Embryology, Carnegie Institution of Washington

In 1902 van Wijhe showed that the cartilaginous skeleton could be demonstrated perfectly in small embryos by staining the specimen with anilin dyes, especially methylene blue, then rendering it transparent in xylol and mounting in Canada balsam. His success was based on the fact that cartilage takes the stain intensely and retains it after the color has been extracted by acid alcohol from all the other tissues. Before the publication of this method it had been necessary, in order to study the morphology of the cartilaginous skeleton, to prepare the embryo in sections and model the skeleton by one of the reconstruction methods. The van Wijhe coloring method possesses a great advantage in that the entire skeleton can be prepared quickly and studied directly, with all parts in their natural connection and the contours of the whole embryo and of the different organs clearly recognizable. On the other hand, the larger specimens, which cannot be mounted in balsam and have to be preserved in xylol, soon lose their transparency and become opalescent.

Two years after the publication of the van Wijhe method, Lundvall introduced some improvements in it that served to make it more adaptable to medium-sized and large objects. He stained the cartilage with toluidin blue in place of methylene blue, and instead of xylol and balsam to render the specimens transparent, he used benzol, from which they were finally transferred to carbon bisulphide. In this fluid even large specimens will remain transparent and can be easily studied.

Both cartilage and bone can be demonstrated by the well-known potassium hydroxide clearing method of Schultze, which method has been used and experimented with in investigations

on the development of the skeletal and vascular systems by Mall, Bardeen, and Hill. Bardeen found that bone and cartilage could be made to stand out prominently by staining the embryo in alum cochineal and subsequently clearing it in potassium hydroxide. Further experience, however, has shown that such preparations are not as clear as specimens successfully prepared by the van Wijhe and Lundvall technique.

After a considerable amount of experimenting, I have found that very satisfactory results can be obtained by combining the use of the stain advocated by Lundvall with the potassium hydroxide clearing method of Schultze. In this way I have succeeded in making brilliant permanent demonstrations of the cartilaginous skeleton in pig, monkey, and human fetuses varying from 20 to 150 mm. (crown-rump length). In view of the fact that the procedure is simple and inexpensive and that it produces uniformly good results, it is to be strongly commended, and an outline of my experience with it may prove of interest to other workers.

FIXATION

Formalin. Most of the human fetuses with which I have experimented had been fixed in 10 per cent formalin solution. Among them were specimens which had been a long time in the solution and whose original condition was poor, with more or less maceration, as well as freshly fixed and well-preserved specimens. Although in the latter the staining reaction to toluidin blue is a little better, the old material nevertheless gave very satisfactory results. With formalin material other stains (alum cochineal, methylene blue, and hematoxylin) yielded poor results. Resorcin fuchsin (Weigert's) gave fair results, but much inferior to toluidin blue, which were uniformly good.

Alcohol. Fresh material fixed for six to ten days in 95 per cent alcohol, so that the embryo was well shriveled, gave excellent results with toluidin blue, as did also specimens that had been preserved for a long time in alcohol.

Bichromate acetic mixture (Müller's fluid to which 10 per cent glacial acetic acid had been added). Fresh specimens up to

40 mm. long fixed in this fluid, or material that had been fixed in it and preserved in 80 per cent alcohol for a considerable time, gave brilliant results with toluidin blue, fair results with methylene blue, and poor results with hematoxylin and with resorcin fuchsin.

STAINING

My best results in all of the various fixatives are unquestionably obtained by the use of Grübler's toluidin blue prepared according to the formula of Lundvall. Smaller embryos are thoroughly stained with it in three days; fetuses 40 mm. long should be left in the stain at room temperature for seven days, which time can be shortened, however, by the thermostat; fetuses 150 mm. long it is necessary to leave in the stain at least ten days. Before staining it is well to take the precaution of neutralizing any residual acid from the formalin by immersing in ammonia water overnight. After staining, the specimen is decolorized in acid alcohol (1 per cent hydrochloric acid in 70 per cent alcohol), which, for small specimens, requires about seven days and for large specimens ten days. The acid alcohol is changed daily until the fluid is only slightly tinged with the extracted stain, and the specimen is then ready for clearing.

Next to toluidin blue, methylene blue gave the most satisfactory results. The disadvantage of this stain, however, is that there is some danger of carrying the decolorization too far. The color is extracted more rapidly by the acid alcohol. Small embryos should not be left in the decolorizing fluid more than two days. A further disadvantage is that the color of the specimen subsequently fades much more rapidly than after toluidin blue. Formalin specimens, stained in resorcin fuchsin, gave fair results. This stain is more resistant to acid alcohol than either methylene blue or toluidin blue, and it is more difficult to thoroughly extract the color from the other tissues; hence the specimens are not so brilliant. Both hematoxylin and alum cochineal were followed by poor results, owing to the difficulty in securing uniform decolorization and to the fact that, in clearing the specimen in potassium hydroxide, the remaining stain was completely removed.

CLEARING

Small embryos can be easily rendered transparent by passing them through the graded alcohols, then benzol, and finally into oil of wintergreen, after the Spalteholz method, or into carbon bisulphide, according to Lundvall. With larger fetuses (over 110 mm. long) we have experienced some difficulty in making them completely transparent. On account of this, resort was had to potassium hydroxide, which usually cleared even the largest specimens and without any detriment to the stain. In one instance (a human fetus 258 mm. long), although the greater part of the specimen cleared satisfactorily, there remained some irregular milky patches which would not clear. Resort was had to absolute alcohol and ether, on the basis that the failure was due to the subcutaneous fat. This treatment, however, did not remove the difficulty, which is still unexplained.

Specimens may be transferred directly from the acid alcohol to 2 per cent potassium hydroxide, but this tends to soften the tissue. It was therefore found better to thoroughly harden the specimen in 95 per cent alcohol before clearing. Embryos 20 mm. long will clear in 2 per cent potassium hydroxide in two days at an average room temperature, after which they should be transferred to 20 per cent glycerin. For fetuses 40 mm. long four days is sufficient. The rapidity with which the specimens become clear is influenced greatly by the temperature; in summer the process is much more rapid than in winter. With large fetuses it is well to start with 2 per cent potassium hydroxide and after two changes to increase the strength to 3 per cent. They should stay in the latter solution until they are transparent, which may require seven days or longer. On transferring to glycerin, if it is found that the specimen is not completely transparent, it can be safely returned to 3 per cent potassium hydroxide for further clearing. After the specimen is cleared it is passed through graded glycerin, beginning with 20 per cent and increasing 20 per cent every two days, until it is finally stored in pure glycerin, to which has been added a crystal of thymol to prevent mold. The clearing of larger specimens is facilitated by removing the brain through the anterior fontanelle and the

viscera through a median incision in the abdomen. In the permanent storing of such material it is well to take the precaution of protecting it from the light. I have some specimens that have been kept in subdued light for two years and which show scarcely any indication of fading.

SUMMARY

The complete method that we are now using in this laboratory for preparing specimens for the demonstration of the cartilaginous skeleton may be summarized as follows:

1. Formalin material is first washed overnight in water to which a few drops of ammonia have been added.

2. Transferred to 70 per cent alcohol, where it is left for from seven to fourteen days, changing the alcohol daily for the first five days.

3. Stained in Lundvall's solution of toluidin blue (Grübler's toluidin blue, 1 gram; alcohol 70 per cent, 400 cc.; HCl, 4 cc.).

4. Decolorized in 70 per cent alcohol, 100 cc.; HCl, 1 cc., for from seven to ten days, until the alcohol is but slightly tinged with the stain.

5. Transferred to 80 per cent alcohol, then to 95 per cent alcohol, three days in each.

6. Transferred to 2 per cent KOH in distilled water, where it is left until cleared, usually two or three days.

7. Transferred to glycerin, 20 per cent, 40 per cent, 60 per cent, and 80 per cent, respectively, in distilled water, two days or more in each; the larger the specimen, the longer it should remain in each grade of glycerin.

8. Stored in pure glycerin to which have been added a few crystals of thymol to prevent mold.

Resumen por el autor, Alexander Gibson.

Nota sobre la persistencia del conducto de Cuvier izquierdo.

El ejemplar objeto de la presente nota fué hallado en un varón de 60 años de edad. Ilustra de modo muy claro la obliteración incompleta del conducto de Cuvier izquierdo; en otras palabras, existe una doble vena cava superior, si bien su calibre es mucho menor que el de la vena cava superior derecha. Esta condición ha sido mencionada unas sesenta veces, pero no se han obtenido datos precisos sobre la frecuencia de su ocurrencia. La explicación de esta anomalía es sencilla si se tiene en cuenta el carácter de los canales venosos que entran en el corazón. Las venas cardinal anterior y posterior se unen a cada lado del cuerpo para formar los conductos de Cuvier. Estos últimos vierten la sangre en el seno venoso del corazón, el conducto izquierdo en el asta izquierda del seno, el derecho en el asta derecha. El asta izquierda del seno no se desarrolla y a consecuencia de esto el conducto de Cuvier izquierdo se atrofia.

Normalmente los únicos restos presentes son la vena oblícua del corazón y el ligamento de la vena cava izquierda, el cual se insinúa entre la vena pulmonar superior izquierda y la superficie inferior de la arteria pulmonar. La vena intercostal superior izquierda representa las porciones terminales de las venas cardinales anterior y posterior. En el sujeto descrito se observa la existencia de un canal venoso permeable que pasa desde la vena intercostal superior izquierda hasta el extremo inferior izquierdo del seno coronario.

NOTE ON A PERSISTENT LEFT DUCT OF CUVIER

ALEXANDER GIBSON
University of Manitoba

ONE FIGURE

The specimen illustrated was obtained from a male subject aged sixty. It illustrates very clearly incomplete obliteration of the left duct of Cuvier; in other words, a double superior vena cava is present, although the calibre of the channel is much less than is that of the right superior vena cava.

The condition has been reported some sixty times. No facts as to the frequency of its occurrence have been obtained. McCotter states that he has observed it once only among seven hundred dissecting-room subjects.

The explanation of the condition is a simple one if reference be made to the venous blood channels entering the heart. On both sides of the body the anterior cardinal vein and posterior cardinal vein unite to form the duct of Cuvier. The duct of Cuvier pours its blood into the sinus portion of the heart, the left duct into the left horn of the sinus, the right duct into the right horn. The left horn of the sinus fails to develop, and coincidently the left duct of cuvier atrophies. Normally, the only remnants present are the oblique vein of the heart, and the ligamentum venae cavae sinistrae, which latter stretches between upper left pulmonary vein and under surface of pulmonary artery. The left superior intercostal vein is the representative of the terminal portions of anterior and posterior cardinal veins.

In this specimen a previous venous channel is seen passing from the left superior intercostal vein down to the left extremity of the coronary sinus. It will be observed to arise from the left superior intercostal vein at a well-marked angle between horizontal and vertical portions of the vein.

The Wilhelm Roux Foundation for Entwicklungsmechanik

The Wilhelm Roux Foundation for Entwicklungsmechanik founded on the seventieth birthday of Wilhelm Roux, consists, first, of a collection of preparations (specimens), apparatus, instruments and books, relating to the mechanics of development, which are available for the use of investigators, teachers and others interested in this science free of charge. Secondly, of an endowment (at present 51,000 Marks) which is to be used to further investigation in Entwicklungsmechanik by contributions of money for scientific work and by prizes for distinguished work in this field. Besides this, it is the intention, as soon as sufficient means are at hand, to provide working places for investigators and thus to found an institute for Entwicklungsmechanik in which courses of instruction may be given.

Those interested in the project are solicited to send appropriate books, specimens for the collection or, possibly also contributions of funds to the

WILHELM ROUX FOUNDATION,
Anatomical Institute,
Halle, a.S., Germany.

The Wistar Institute solicits, from American investigators and publishers, contributions of reprints relating to the field of Entwicklungsmechanik for the Wilhelm Roux Foundation.

All such contributions may be sent directly to Dr. Geo. Wetzel, custodian of the Roux Collection and Library, Anatomical Institute, Halle a.S., Germany, or such material will be forwarded if sent to The Wistar Institute, 36th and Woodland Avenue, Philadelphia, Pa.
